Longitudinal versus cross-sectional research. In a longitudinal study of development between ages 6 and 10, the same children would be observed at 6, again at 8, and again at 10. In a cross-sectional study of the same age span, a group of 6-year-olds, a group of 8-year-olds, and a group of 10-year-olds would be compared simultaneously. Note that data collection could be completed immediately in the cross-sectional study, whereas the longitudinal study would require 4 years to complete.

reactivity was moderate. *Difficult children* constituted 10% of the group. They tended to be glum, erratic in sleep and eating, resistant to change, and relatively irritable. The remaining 35% of the children showed mixtures of these three temperaments.

A child's temperament at 3 months was a fair predictor of the child's temperament at age 10. Infants categorized as "difficult" developed more emotional problems requiring counseling than other children did. Although basic changes in temperament were seen in some children, temperament was generally stable over time (Chess & Thomas, 1996).

Some critics have expressed concern because Thomas and Chess's data were based on parents' highly subjective ratings of their children's temperament (Martin & Fox, 2006). But other investigators, using a variety of methods to assess infant temperament, have also found it to be fairly stable (Rothbart & Bates, 2006; Sanson, Hemphill, & Smart, 2002). However, the evidence indicates that temperament tends to stabilize a little later (around age 1 or 2) than Thomas and Chess suggested (Thompson & Goodvin, 2005).

One prominent example of contemporary research on temperament is the work of Jerome Kagan and his colleagues, who have relied on direct observations of children in their studies (Kagan & Snidman, 1991; Kagan, Snidman, & Arcus, 1992). They have found that about 15%–20% of infants display an *inhibited temperament* characterized by shyness, timidity, and wariness of unfamiliar people, objects, and events. In contrast, about 25%–30% of infants exhibit an *uninhibited temperament* (the remainder fall in between these extremes). These children are less restrained, approaching unfamiliar people, objects, and events with little trepidation. Evidence suggests that these temperamental styles have a genetic basis and are reasonably stable into young adulthood (Kagan, 2004; Kagan, Reznick, & Snidman, 1999).

Moreover, recent research suggests that infant temperament lays the foundation for personality traits in adulthood (Rothbart, 2007). For example, a large-scale, longitudinal study that began with 1037 3-year-old children in 1972–1973 conducted personality assessments of the participants many years later when they reached the age of 26 (Caspi et al., 2003). The 3-year-olds had been classified into five temperament types: inhibited, undercontrolled, confident, reserved, and well-adjusted. At age 26, these temperaments had significant predictive effects on all three higher-order personality traits examined. These data provide the "longest and strongest evidence to date" that early temperamental characteristics can foretell the contours of adult personality.

A child's temperament can influence parental reactions, which can have some effect on the child's temperament. For example, parents tend to play more vigorously with children who are temperamentally active, which may help to make them more active.

Although temperament is heavily influenced by heredity and tends to be fairly stable over time, theorists emphasize that temperament is not unchangeable (Thompson, Easterbrooks, & Padilla-Walker, 2003). Parental reactions and other social experiences can gradually massage a child's temperamental characteristics. As Kagan (2004) puts it, "There is no fixed determinism between an infant temperament and what that child will become 20 years later. Temperament is not destiny" (p. 65).

Early Emotional Development: Attachment

Do mothers and infants forge lasting emotional bonds in the first few hours after birth? Do early emotional bonds affect later development? These are just two of the questions investigated by psychologists interested in attachment. *Attachment* **refers to the close, emotional bonds of affection that develop between infants and their caregivers.** Researchers have shown a keen interest in how infant-mother attachments are formed early in life. Children eventually may form attachments to many people, including their fathers, grandparents, and others (Cassidy, 1999). However, a child's first important attachment

Jerome Kagan

"Every psychological quality in an adult can be likened to a pale gray fabric woven from thin black threads representing biology and white threads representing experience, neither visible in the homogeneously gray cloth."

usually occurs with his or her mother because in most cultures she is the principal caregiver, especially in the early years of life (Lamb et al., 1999).

Contrary to popular belief, infants' attachment to their mothers is *not* instantaneous. Initially, babies show relatively little in the way of a special preference for their mothers. At 2–3 months of age, infants may smile and laugh more when they interact with their mother, but they generally can be handed over to strangers such as babysitters with little difficulty. This situation gradually changes, and by about 6–8 months, infants begin to show a pronounced preference for their mother's company and often protest when separated from her (Lamb, Ketterlinus, & Fracasso, 1992). This is the first manifestation of *separation anxiety*—**emotional distress seen in many infants when they are separated from people with whom they have formed an attachment.** Separation anxiety, which may occur with fathers and other familiar caregivers as well as with mothers, typically peaks at around 14–18 months and then begins to decline.

Theories of Attachment   9e
Why do children gradually develop a special attachment to their mothers? This question sounds simple enough, but it has been the subject of a lively theoretical dialogue. Behaviorists have argued that the infant-mother attachment develops because mothers are associated with the powerful, reinforcing event of being fed. Thus, the mother becomes a conditioned reinforcer. This reinforcement theory of attachment came into question as a result of Harry Harlow's famous studies of attachment in infant rhesus monkeys (Harlow, 1958, 1959).

Harlow removed monkeys from their mothers at birth and raised them in the laboratory with two types of artificial "substitute mothers." One type of artificial mother was made of terrycloth and could provide "contact comfort" (see the photo above). The other type of artificial mother was made of wire. Half of the monkeys were fed from a bottle attached to a wire mother and the other half were fed by a cloth mother. The young monkeys' attachment to their substitute mothers was tested by introducing a frightening stimulus, such as a strange toy. If reinforcement through feeding were the key to attachment, the frightened monkeys should have scampered off to the mother that had fed them. This was not the case. The young monkeys scrambled for their cloth mothers, who had provided contact comfort, even if they were *not* fed by them.

Harlow's work seriously undermined the behaviorists' reinforcement explanation of attachment. Attention then turned to an alternative explanation

Even if fed by a wire surrogate mother, the Harlows' infant monkeys cuddled up with a terry cloth surrogate that provided contact comfort. When threatened by a frightening toy, the monkeys sought security from their terry cloth mothers.

of attachment proposed by John Bowlby (1969, 1973, 1980). Bowlby was impressed by the importance of contact comfort to Harlow's monkeys and by the apparently unlearned nature of this preference. Influenced by evolutionary theories, Bowlby argued that there must be a biological basis for attachment. According to his view, infants are biologically programmed to emit behavior (smiling, cooing, clinging, and so on) that triggers an affectionate, protective response from adults. Bowlby also asserted that adults are programmed by evolutionary forces to be captivated by this behavior and to respond with warmth, love, and protection. Obviously, these characteristics would be adaptive in terms of promoting children's survival. Bowlby's theory has guided most of the research on attachment over the last several decades, including Mary Ainsworth's influential work on patterns of attachment.

Patterns of Attachment   9e
Research by Mary Ainsworth and her colleagues (Ainsworth, 1979; Ainsworth et al., 1978) demonstrated that infant-mother attachments vary in quality. Ainsworth found that attachments fall into three categories (see **Figure 11.5** on the next page). Fortunately, most infants develop a *secure attachment.* These infants use their mother as a secure base from which to venture out and explore the world. They play comfortably with their mother present, become visibly upset when she leaves, and are quickly calmed by her return. However, some children display a pattern called *anxious-ambivalent attachment* (also
Harry Harlow

"The little we know about love does not transcend simple observation, and the little we write about it has been written better by poets and novelists."
John Bowlby

"The only relevant criterion by which to consider the natural adaptedness of any particular part of present-day man's behavioural equipment is the degree to which and the way in which it might contribute to population survival in man's primeval environment."

Mary Salter Ainsworth

"Where familial security is lacking, the individual is handicapped by the lack of what might be called a secure base from which to work."

called *resistant* attachment). They appear anxious even when their mothers are near and protest excessively when she leaves, but they are not particularly comforted when she returns. Children in the third category seek little contact with their mothers and often are not distressed when she leaves, a condition labeled *avoidant attachment.* Years later, other researchers added a fourth category called *disorganized-disoriented* attachment (Main & Solomon, 1986, 1990). These children appear confused about whether they should approach or avoid their mother and are especially insecure (Lyons-Ruth & Jacobvitz, 1999).

Maternal behaviors appear to have considerable influence over the type of attachment that emerges between an infant and mother (Ainsworth et al., 1978; Posada et al., 2007). Mothers who are sensitive and responsive to their children's needs are more likely to promote secure attachments than mothers who are relatively insensitive or inconsistent in their responding (Nievar & Becker, 2008; van den Boom, 2001). However, infants are not passive bystanders as this process unfolds. They are active participants who influence the process with their crying, smiling, fussing, and babbling. Temperamentally difficult infants who spit up most of their food, make bathing a major battle, and rarely smile may sometimes slow the process of attachment (van IJzendoorn & Bakermans-Kranenburg, 2004). Thus, the type of attachment that emerges between an infant and mother may depend on the nature of the infant's temperament as well as the mother's sensitivity (Kagan & Fox, 2006).

How stable are the various patterns of attachment over time? The results of research on attachment stability vary considerably, depending on the way attachment is measured, the nature of the sample, and the time interval examined (Thompson, 1998, 2000). Overall, attachment types tend to be moder-

ately stable through childhood and into adulthood (Ammaniti, Speranza, & Fedele, 2005; Fraley, 2002). When changes in attachment type are seen, they often reflect changed circumstances in youngsters' lives, such as increases in family stress or alterations in parental support.

Evidence suggests that the quality of the attachment relationship can have important consequences for children's subsequent development. Based on their attachment experiences, children develop *internal working models* of the dynamics of close relationships that influence their future interactions with a wide range of people (Bretherton & Munholland, 1999). Infants with a relatively secure attachment *tend* to become resilient, sociable, competent toddlers with high self-esteem (Ranson & Urichuk, 2006; Thompson, 1999a). In their preschool years, they display more persistence, curiosity, self-reliance, and leadership and have better peer relations (Weinfield et al., 1999) while experiencing fewer negative emotions and more positive emotions (Kochanska, 2001). In middle childhood, those who had secure attachments in infancy exhibit higher levels of positive moods, healthier strategies for coping with stress, and better regulation of their emotions (Kerns et al., 2007). Studies have also found a relationship between secure attachment and more advanced cognitive development during childhood and adolescence (Ranson & Urichuk, 2006). However, it is worth noting that all the relevant data on attachment effects are correlational (experimenters cannot manipulate caregiver-infant attachments), so we cannot assume that secure attachment *causes* all these favorable outcomes. Secure attachment could co-vary with other important factors that contribute to high self-esteem, self-reliance, and so forth.

The repercussions of attachment patterns in infancy appear to even reach into adulthood. In Chap-

ter 16 we'll discuss thought-provoking evidence that infant attachment patterns set the tone for people's romantic relationships in adulthood, not to mention their gender roles, religious beliefs, and patterns of self-disclosure (Kirkpatrick, 2005; Mikulincer, 2006; Mikulincer & Shaver, 2007; Schwartz, Waldo, & Higgins, 2004; Shaver & Hazan, 1993, 1994).

Day Care and Attachment

The impact of day care on attachment has been the subject of considerable debate. Some theorists have argued that frequent infant-mother separations might disrupt the attachment process (Belsky, 1988, 1992). The issue is an important one, given that the vast majority of the children under age 5 in the United States receive some nonmaternal care, and by age 2, 43% are in *full-time* (more than 35 hours per week) day care (Phillips, McCartney, & Sussman, 2006). To explore this question and other issues related to day care, a major, long-term study was launched in the United States in the 1990s by the National Institute of Child Health and Human Development (NICHD). Some of the early findings from this 10-site study of over 1300 children lent credence to concerns about day care and attachment. For example, infants were found to be more likely to develop insecure attachments when low-quality day care was paired with low levels of maternal sensitivity (NICHD, 1997). And more time in nonmaternal care was found to be associated with elevated levels of aggression and disobedience in preschoolers (NICHD, 2003).

That said, the magnitude of these effects tended to be small, and some of the effects had diminished further by the time the children reached the sixth grade (Belsky et al., 2007). Although some researchers have expressed concern about children who spend long hours in day care (Belsky, 2006), the overall evidence suggests that nonmaternal care is not harmful to children's social and emotional development (NICHD, 2006). In fact, research has uncovered some *favorable* outcomes associated with day care. Children exposed to *high-quality* day care tend to show more advanced cognitive development, language skills, and school readiness (NICHD, 2006). Once again, the effects are relatively small in magnitude, but they do suggest that it is prudent for parents to seek high-quality day care for their children (Belsky, 2006).

Culture and Attachment   9e

Separation anxiety emerges in children at about 6–8 months and peaks at about 14–18 months in cultures around the world (Grossmann & Grossmann, 1990). These findings, which have been replicated in quite a variety of non-Western cultures, suggest that
Figure 11.6

Cultural variations in attachment patterns. This graph shows the distribution of the three original attachment patterns found in specific studies in Germany, Japan, and the United States. As you can see, secure attachment is the most common pattern in all three societies, as it is around the world. However, there are some modest cultural differences in the prevalence of each pattern of attachment, which are probably attributable to cultural variations in childrearing practices. (Data from van IJzendoorn & Kroonenberg, 1988)

attachment is a universal feature of human development. However, studies have found some modest cultural variations in the proportion of infants who fall into the three attachment categories described by Ainsworth. Working mostly with white, middle-class subjects in the United States, researchers have found that 67% of infants display a secure attachment, 21% an avoidant attachment, and 12% an anxious-ambivalent attachment (the fourth attachment pattern mentioned earlier is not included here because it has only been tracked in a minority of cross-cultural studies) (van IJzendoorn & Sagi, 1999). Interestingly, studies in Japan and Germany have yielded somewhat different estimates of the prevalence of various types of attachment, as shown in **Figure 11.6**. Nonetheless, the differences are small and secure attachment appears to be the predominant type of attachment around the world.

Becoming Unique: Personality Development   9b

How do individuals develop their unique constellations of personality traits over time? Many theories have addressed this question. The first major theory of personality development was constructed by Sigmund Freud back around 1900. As we'll discuss in Chapter 12, he claimed that the basic foundation of an individual's personality is firmly laid down by age 5. Half a century later, Erik Erikson (1963) proposed a sweeping revision of Freud's theory that has proven influential. Like Freud, Erikson concluded that events in early childhood leave a permanent stamp on adult personality. However, unlike Freud,
Erik Erikson

"Human personality in principle develops according to steps predetermined in the growing person's readiness to be driven toward, to be aware of, and to interact with a widening social radius."

Continuous development

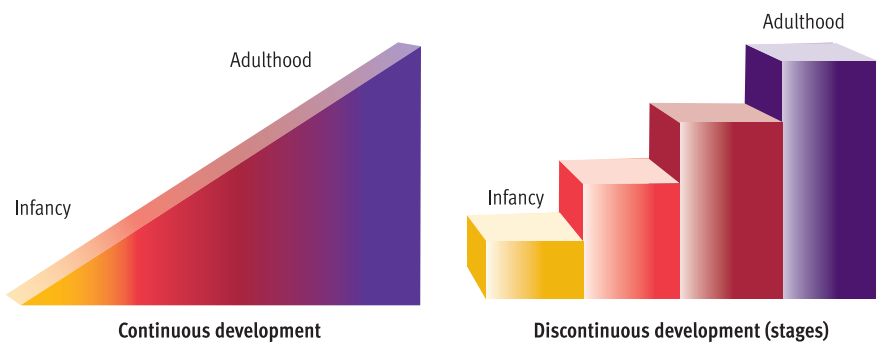
Discontinuous development (stages)


Figure 11.7
Stage theories of development. Some theories view development as a relatively continuous process, albeit not as smooth and perfectly linear as depicted on the left. In contrast, stage theories assume that development is marked by major discontinuities (as shown on the right) that bring fundamental, qualitative changes in capabilities or characteristic behavior.

Erikson theorized that personality continues to evolve over the entire life span.

Building on Freud's earlier work, Erikson devised a stage theory of personality development. As you'll see in reading this chapter, many theories describe development in terms of stages. A *stage* is a developmental period during which characteristic patterns of behavior are exhibited and certain capacities become established. Stage theories assume that (1) individuals must progress through specified stages in a particular order because each stage builds on the previous stage, (2) progress through these stages is strongly related to age, and (3) development is marked by major discontinuities that usher in dramatic transitions in behavior (see **Figure 11.7**).

Erikson's Stage Theory   9b

Erikson partitioned the life span into eight stages, each of which brings a *psychosocial crisis* involving transitions in important social relationships. According to Erikson, personality is shaped by how individuals deal with these psychosocial crises. Each crisis involves a struggle between two opposing tendencies, such as trust versus mistrust or ini-

tiative versus guilt, both of which are experienced by the person. Erikson described the stages in terms of these antagonistic tendencies, which represent personality traits that people display in varying degrees over the remainder of their lives. Although the names for Erikson's stages suggest either-or outcomes, he viewed each stage as a tug of war that determined the subsequent *balance* between opposing polarities in personality. All eight stages in Erikson's theory are charted in **Figure 11.8**. We describe the first four childhood stages here and discuss the remaining stages in the upcoming sections on adolescence and adulthood.

Trust Versus Mistrust.   Erikson's first stage encompasses the first year of life, when an infant has to depend completely on adults to take care of its basic needs for such necessities as food, a warm blanket, and changed diapers. If an infant's basic biological needs are adequately met by his or her caregivers and sound attachments are formed, the child should develop an optimistic, trusting attitude toward the world. However, if the infant's basic needs are taken care of poorly, a more distrusting, pessimistic personality may result.

Autonomy Versus Shame and Doubt.   Erikson's second stage unfolds during the second and third years of life, when parents begin toilet training and other efforts to regulate the child's behavior. The child must begin to take some personal responsibility for feeding, dressing, and bathing. If all goes well, he or she acquires a sense of self-sufficiency. But, if parents are never satisfied with the child's efforts and there are constant parent-child conflicts, the child may develop a sense of personal shame and self-doubt.

Figure 11.8
Erikson's stage theory. Erikson's theory of personality development posits that people evolve through eight stages over the life span. Each stage is marked by a *psychosocial crisis* that involves confronting a fundamental question, such as "Who am I and where am I going?" The stages are described in terms of alternative traits that are potential outcomes from the crises. Development is enhanced when a crisis is resolved in favor of the healthier alternative (which is listed first for each stage).

Stage 1	Stage 2	Stage 3	Stage 4	Stage 5	Stage 6	Stage 7	Stage 8
Trust versus mistrust	Autonomy versus shame and doubt	Initiative versus guilt	Industry versus inferiority	Identity versus confusion	Intimacy versus isolation	Generativity versus self-absorption	Integrity versus despair
Is my world predictable and supportive?	Can I do things myself or must I always rely on others?	Am I good or am I bad?	Am I competent or am I worthless?	Who am I and where am I going?	Shall I share my life with another or live alone?	Will I produce something of real value?	Have I lived a full life?
First year of life	Second and third years	Fourth through sixth years	Age 6 through puberty	Adolescence	Early adulthood	Middle adulthood	Late adulthood

Initiative Versus Guilt. In Erikson's third stage, lasting roughly from ages 3 to 6, children experiment and take initiatives that may sometimes conflict with their parents' rules. Overcontrolling parents may begin to instill feelings of guilt, and self-esteem may suffer. Parents need to support their children's emerging independence while maintaining appropriate controls. In the ideal situation, children will retain their sense of initiative while learning to respect the rights and privileges of other family members.

Industry Versus Inferiority. In the fourth stage (age 6 through puberty), the challenge of learning to function socially is extended beyond the family to the broader social realm of the neighborhood and school. Children who are able to function effectively in this less nurturant social sphere where productivity is highly valued should learn to value achievement and to take pride in accomplishment, resulting in a sense of competence. Or, if things don't go well in this broader social domain, they may develop a sense of inferiority.

Evaluating Erikson's Theory

The strength of Erikson's theory is that it accounts for both continuity and transition in personality development. It accounts for transition by showing how new challenges in social relations stimulate personality development throughout life. It accounts for continuity by drawing connections between early childhood experiences and aspects of adult personality. One measure of a theory's value is how much research it generates, and Erikson's theory continues to guide a fair amount of research (Thomas, 2005).

On the negative side of the ledger, Erikson's theory has depended heavily on illustrative case studies, which are open to varied interpretations (Thomas, 2005). Another weakness is that the theory provides an "idealized" description of "typical" developmental patterns. Thus, it's not well suited for explaining the enormous personality differences that exist among people. Inadequate explanation of individual differences is a common problem with stage theories of development. This shortcoming surfaces again in the next section, where we'll examine Jean Piaget's stage theory of cognitive development.

The Growth of Thought: Cognitive Development

9c

Cognitive development **refers to transitions in youngsters' patterns of thinking, including reasoning, remembering, and problem solving.** The

investigation of cognitive development was dominated in most of the second half of the 20th century by the theory of Jean Piaget (Kessen, 1996). Much of our discussion of cognitive development is devoted to Piaget's theory and the research it generated, although we'll also delve into other approaches.

Overview of Piaget's Stage Theory

9c

Jean Piaget (1929, 1952, 1983) was an interdisciplinary scholar whose own cognitive development was exceptionally rapid. In his early 20s, after he had earned a doctorate in natural science and published a novel, Piaget turned his focus to psychology. He soon found himself administering intelligence tests to children to develop better test norms. In doing this testing, Piaget became intrigued by the reasoning underlying the children's *wrong* answers. He decided that measuring children's intelligence was less interesting than studying how children *use* their intelligence. He spent the rest of his life studying cognitive development. Many of his ideas were based on insights gleaned from careful observations of his own three children during their infancy.

Like Erikson's theory, Piaget's model is a *stage theory* of development. Piaget proposed that youngsters progress through four major stages of cognitive development, which are characterized by fundamentally different thought processes: (1) the *sensorimotor period* (birth to age 2), (2) the *preoperational period* (ages 2 to 7), (3) the *concrete operational period* (ages 7 to 11), and (4) the *formal operational period* (age 11 onward). **Figure 11.9** on the next page provides an overview of each of these periods. Piaget regarded his age norms as approximations and acknowledged that transitional ages may vary, but he was convinced that all children progress through the stages of cognitive development in the same order.

According to Erik Erikson, school-age children face the challenge of learning how to function in social situations outside of their family, especially with peers and at school. If they succeed, they will develop a sense of competence; if they fail, they may feel inferior.

© Farrell Grehan/Corbis

Jean Piaget

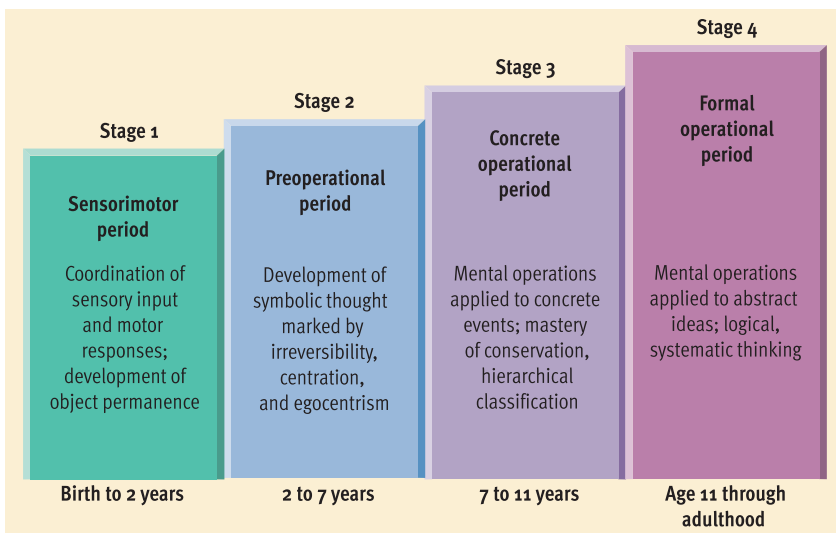
"It is virtually impossible to draw a clear line between innate and acquired behavior patterns."


Figure 11.9
Piaget's stage theory. Piaget's theory of cognitive development identifies four stages marked by fundamentally different modes of thinking through which youngsters evolve. The approximate age norms and some key characteristics of thought at each stage are summarized here.

Sensorimotor Period. One of Piaget's foremost contributions was to greatly enhance our understanding of mental development in the earliest months of life. The first stage in his theory is the *sensorimotor period,* which lasts from birth to about age 2. Piaget called this stage *sensorimotor* because infants are developing the ability to coordinate their sensory input with their motor actions. The major development during the sensorimotor stage is the gradual appearance of symbolic thought. At the beginning of this stage, a child's behavior is dominated by innate reflexes. But by the end of the stage, the child can use mental symbols to represent objects (for example, a mental image of a favorite toy). The key to this transition is the acquisition of the concept of object permanence.

Figure 11.10
Piaget's conservation task for liquid. After watching the transformation shown, a preoperational child will usually answer that the taller beaker contains more water. In contrast, a child in the concrete operational period tends to respond correctly, recognizing that the amount of water in beaker C remains the same as the amount in beaker A.

Object permanence **develops when a child recognizes that objects continue to exist even when they are no longer visible.** Although you surely take the permanence of objects for granted, infants aren't aware of this permanence at first. If you show a 4-month-old an eye-catching toy and then cover the toy with a pillow, the child will not attempt to search for the toy. Piaget inferred from this observation that the child does not understand that the toy continues to exist under the pillow. The notion of object permanence does not dawn on children overnight. According to Piaget, the first signs of this insight usually appear between 4 and 8 months of age, when children will often pursue an object that is *partially* covered in their presence. Progress is gradual, and Piaget believed that children typically don't master the concept of object permanence until they're about 18 months old.

Preoperational Period. During the *preoperational period,* which extends roughly from age 2 to age 7, children gradually improve in their use of mental images. Although progress in symbolic thought continues, Piaget emphasized the *shortcomings* in preoperational thought.

Consider a simple problem that Piaget presented to youngsters. He would take two identical beakers and fill each with the same amount of water. After a child had agreed that the two beakers contained the same amount of water, he would pour the water from one of the beakers into a much taller and thinner beaker (see **Figure 11.10**). He would then ask the child whether the two differently shaped beakers still contained the same amount of water. Confronted with a problem like this, children in the preoperational period generally said no. They typically focused on the higher water line in the taller beaker and insisted that there was more water in the slender beaker. They had not yet mastered the principle of conservation. *Conservation* **is Piaget's term for the awareness that physical quantities remain constant in spite of changes in their shape or appearance.**

Why are preoperational children unable to solve conservation problems? According to Piaget, their inability to understand conservation is caused by some basic flaws in preoperational thinking. These flaws include centration, irreversibility, and egocentrism.

Centration **is the tendency to focus on just one feature of a problem, neglecting other important aspects.** When working on the conservation problem with water, preoperational children tend to concentrate on the height of the water while ignoring the width. They have difficulty focusing on several aspects of a problem at once.

Irreversibility **is the inability to envision reversing an action.** Preoperational children can't mentally "undo" something. For instance, in grappling with the conservation of water, they don't think about what would happen if the water were poured back from the tall beaker into the original beaker.

Egocentrism **in thinking is characterized by a limited ability to share another person's viewpoint.** Indeed, Piaget felt that preoperational children fail to appreciate that there are points of view other than their own. For instance, if you ask a preoperational girl whether her sister has a sister, she'll probably say no if they are the only two girls in the family. She's unable to view sisterhood from her sister's perspective.

A notable feature of egocentrism is **animism— the belief that all things are living,** just like oneself. Thus, youngsters attribute lifelike, human qualities to inanimate objects, asking questions such as, "When does the ocean stop to rest?" or "Why does the wind get so mad?"

As you can see, Piaget emphasized the weaknesses apparent in preoperational thought. Indeed, that is why he called this stage *pre*operational. The ability to perform *operations*—internal transformations, manipulations, and reorganizations of mental structures—emerges in the next stage.

Concrete Operational Period. The development of mental operations marks the beginning of the *concrete operational period,* which usually lasts from about age 7 to age 11. Piaget called this stage *concrete* operations because children can perform operations only on images of tangible objects and actual events.

Among the operations that children master during this stage are reversibility and decentration. *Reversibility* permits a child to mentally undo an action. *Decentration* allows the child to focus on more than one feature of a problem simultaneously. The newfound ability to coordinate several aspects of a problem helps the child appreciate that there are several ways to look at things. This ability in turn leads to a *decline in egocentrism* and *gradual mastery of conservation* as it applies to liquid, mass, number, volume, area, and length (see **Figure 11.11**).

Typical tasks used to measure conservation		Typical age of mastery
Conservation of number Two equivalent rows of objects are shown to the child, who agrees that they have the same number of objects.		6–7
One row is lengthened, and the child is asked whether one row has more objects.		
Conservation of mass The child acknowledges that two clay balls have equal amounts of clay.		7–8
The experimenter changes the shape of one of the balls and asks the child whether they still contain equal amounts of clay.		
Conservation of length The child agrees that two sticks aligned with each other are the same length.		7–8
After moving one stick to the left or right, the experimenter asks the child whether the sticks are of equal length.		
Conservation of area Two identical sheets of cardboard have wooden blocks placed on them in identical positions; the child confirms that the same amount of space is left on each piece of cardboard.		8–9
The experimenter scatters the blocks on one piece of cardboard and again asks the child whether the two pieces have the same amount of unoccupied space.		

Figure 11.11
The gradual mastery of conservation. Children master conservation during the concrete operational period, but their mastery is gradual. As outlined here, children usually master the conservation of number at age 6 or 7, but they may not understand the conservation of area until age 8 or 9.

As children master concrete operations, they develop a variety of new problem-solving capacities. Let's examine another problem studied by Piaget. Give a preoperational child seven carnations and three daisies. Tell the child the names for the two types of flowers and ask the child to sort them into carnations and daisies. That should be no problem. Now ask the child whether there are more carnations or more daisies. Most children will correctly respond that there are more carnations. Now ask the child whether there are more carnations or more flowers. At this point, most preoperational children will stumble and respond incorrectly that there are more carnations than flowers. Generally, preoperational children can't handle *hierarchical classification* problems that require them to focus simultaneously on two levels of classification. However, the child who has advanced to the concrete operational stage is not as limited by centration and can work successfully with hierarchical classification problems.

Formal Operational Period. The final stage in Piaget's theory is the *formal operational period,* which typically begins around 11 years of age. In this stage, children begin to apply their operations to *abstract* concepts in addition to concrete objects. Indeed, during this stage, youngsters come to *enjoy* the heady contemplation of abstract concepts. Many adolescents spend hours mulling over hypothetical possibilities related to abstractions such as justice, love, and free will.

According to Piaget, youngsters graduate to relatively adult modes of thinking in the formal operations stage. He did *not* mean to suggest that no further cognitive development occurs once children reach this stage. However, he believed that after children achieve formal operations, further developments in thinking are changes in *degree* rather than fundamental changes in the *nature* of thinking.

Adolescents in the formal operational period become more *systematic* in their problem-solving efforts. Children in earlier developmental stages tend to attack problems quickly, with a trial-and-error approach. In contrast, children who have achieved formal operations are more likely to think things through. They envision possible courses of action and try to use logic to reason out the likely consequences of each possible solution before they act. Thus, thought processes in the formal operational period can be characterized as abstract, systematic, logical, and reflective.

Evaluating Piaget's Theory

Jean Piaget made a landmark contribution to psychology's understanding of children in general and their cognitive development in particular (Beilin, 1992). He founded the field of cognitive development and fostered a new view of children that saw them as active agents constructing their own worlds (Fischer & Hencke, 1996). Above all else, he sought answers to new questions. As he acknowledged in a 1970 interview, "It's just that no adult ever had the idea of asking children about conservation. It was so obvious that if you change the shape of an object, the quantity will be conserved. Why ask a child? The novelty lay in asking the question" (Hall, 1987, p. 56). Piaget's theory guided an enormous volume of productive research that continues through today (Brainerd, 1996; Feldman, 2003). This research has supported many of Piaget's central propositions (Flavell, 1996). In such a far-reaching theory, however, there are bound to be some weak spots. Here are some of the criticisms of Piaget's theory:

1. In many areas, Piaget appears to have underestimated young children's cognitive development (Birney et al., 2005). For example, researchers have found evidence that children begin to develop object permanence much earlier than Piaget thought, perhaps as early as 3 to 4 months of age (Baillargeon, 2002; Wang, Baillargeon, & Paterson, 2005). Others have marshaled evidence that preoperational children exhibit less egocentrism than Piaget believed (Newcombe & Huttenlocher, 1992).

2. Piaget's model suffers from problems that plague most stage theories. Like Erikson, Piaget had little to say about individual differences in development (Siegler, 1994). Also, people often simultaneously display patterns of thinking that are characteristic of several stages. This "mixing" of stages and the fact that the transitions between stages are grad-

ual rather than abrupt call into question the value of organizing development in terms of stages (Courage & Howe, 2002; Krojgaard, 2005).

3. Piaget believed that his theory described universal processes that should lead children everywhere to progress through uniform stages of thinking at roughly the same ages. Subsequent research has shown that the *sequence* of stages is largely invariant, but the *timetable* that children follow in passing through these stages varies considerably across cultures (Dasen, 1994; Rogoff, 2003). Thus, Piaget underestimated the influence of cultural factors on cognitive development. Indeed, it is probably fair to say that Piaget underestimated the importance of environmental factors in general while focusing too heavily on the role of maturation (Birney et al., 2005; Maratsos, 2007).

Vygotsky's Sociocultural Theory

In recent decades, as the limitations and weaknesses of Piaget's ideas have become more apparent, some developmental researchers have looked elsewhere for theoretical guidance. Ironically, the theory that has recently inspired the greatest interest—Lev Vygotsky's *sociocultural theory*—dates back to around the same time that Piaget began formulating his theory (1920s–1930s). Vygotsky was a prominent Russian psychologist whose research ended prematurely in 1934 when he died of tuberculosis at the age of 37. Western scientists had little exposure to his ideas until the 1960s, and it was only in 1986 that a complete version of his principal book (Vygotsky, 1934) was published in English. Working in a perilous political climate in the post-Revolution Soviet Union, Vygotsky had to devise a theory that would not be incompatible with the Marxist social philosophy that ruled communist thinking (Thomas, 2005). Given the constraints placed on his theorizing, one might expect that 70 years later his ideas would not resonate with contemporary psychologists in capitalist societies, but the reality is just the opposite, as his theory has become very influential (Daniels, 2005; Feldman, 2003).

Vygotsky's and Piaget's perspectives on cognitive development have much in common, but they also differ in several important respects (DeVries, 2000; Matusov & Hayes, 2000; Rowe & Wertsch, 2002). First, in Piaget's theory, cognitive development is primarily fueled by individual children's active exploration of the world around them. The child is viewed as the agent of change. In contrast, Vygotsky places enormous emphasis on how children's cognitive development is fueled by social interactions with parents, teachers, and older children who can provide invaluable guidance (Hedegaard, 2005). Second,

© Richard Hutchings/Photo Researchers, Inc.

Piaget viewed cognitive development as a universal process that should unfold in largely the same way across widely disparate cultures. Vygotsky, on the other hand, asserted that culture exerts great influence over how cognitive growth unfolds (Wertsch & Tulviste, 2005). For example, the cognitive skills acquired in literate cultures that rely on schools for training will differ from those acquired in tribal societies where there may be no formal schooling. Third, Piaget viewed children's gradual mastery of language as just another aspect of cognitive development, whereas Vygotsky argued that language acquisition plays a crucial, central role in fostering cognitive development (Kozulin, 2005).

According to Vygotsky, children acquire most of their culture's cognitive skills and problem-solving strategies through collaborative dialogues with more experienced members of their society. He saw cognitive development as more like an *apprenticeship* than a journey of individual discovery. His emphasis on the social origins of cognitive development is apparent in his concept of the *zone of proximal development*. **The *zone of proximal development (ZPD)* is the gap between what a learner can accomplish alone and what he or she can achieve with guidance from more skilled partners.** For example, a young child learning to run a personal computer, working solo, will be stymied in many ways and may

Vygotsky and Piaget differ about the importance of private speech, young children's tendency to talk to themselves as they go about their business. Piaget viewed private speech as insignificant, whereas Vygotsky asserted that children use private speech to regulate their actions and plan their strategies.

Archives of the History of American Psychology, University of Akron, Akron, Ohio

Lev Vygotsky

"In the process of development the child not only masters the items of cultural experience but the habits and forms of cultural behaviour, the cultural methods of reasoning."

Theories of Development

Maintained by the Psychology Department at George Mason University, this site is an excellent resource, providing links to many other sites that focus on influential theories of human development. Starting here, a visitor can learn a great deal about the ideas of Erik Erikson, Jean Piaget, Lev Vygotsky, and Lawrence Kohlberg.
Figure 11.12

The procedure used to test infants' understanding of number. To see if 5-month-old infants have some appreciation of addition and subtraction, Wynn (1992, 1996) showed them sequences of events like those depicted here. If children express surprise (primarily assessed by time spent looking) when the screen drops and they see only one object, this result suggests that they understand that 1 + 1 = 2. Wynn and others have found that infants seem to have some primitive grasp of simple addition and subtraction.

SOURCE: Adapted from Wynn, K. (1992). Addition and subtraction by human infants. *Nature, 358,* 749–750. Copyright © 1992 Macmillan Magazines, Ltd. Reprinted with permission.

quickly reach a point at which progress is stalled. But the same child may progress much further with a judicious hint here or there from an experienced computer user. The ZPD for a task is the area in which new cognitive growth is likely. Vygotsky's emphasis on the primacy of language is reflected in his discussion of *private speech*. Preschool children talk aloud to themselves a lot as they go about their activities. Piaget viewed this speech as egocentric and insignificant. Vygotsky argued that children use this private speech to plan their strategies, regulate their actions, and accomplish their goals. As children grow older, this private speech is internalized and becomes the normal verbal dialogue that people have with themselves as they go about their business. Thus, language increasingly serves as the *foundation* for youngsters' cognitive processes.

Vygotsky's sociocultural theory is guiding a great deal of contemporary research on cognitive develop-

ment (Feldman, 2003). This research has provided empirical support for many of Vygotsky's ideas (Rogoff, 1998; Winsler, 2003). Like Piaget's theory, Vygotsky's perspective promises to enrich our understanding of how children's thinking develops and matures.

Are Some Cognitive Abilities Innate?

The frequent finding that Piaget underestimated infants' cognitive abilities has led to a rash of studies suggesting that infants have a surprising grasp of many complex concepts. Studies have demonstrated that infants understand basic properties of objects and some of the rules that govern them (Baillargeon, 2004). At 3 to 4 months of age, infants understand that objects are distinct entities with boundaries, that objects move in continuous paths, that one solid object cannot pass through another, that an object cannot pass through an opening that is smaller than the object, and that objects on slopes roll down rather than up (Baillargeon, 2008; Spelke & Newport, 1998).

In this line of research, perhaps the most stunning discovery has been the finding that *infants seem to exhibit surprisingly sophisticated numerical abilities* (Lipton & Spelke, 2004; Wood & Spelke, 2005). For example, Karen Wynn (1992, 1996) has conducted some groundbreaking studies of infants' numerical capabilities. She demonstrated that if 5-month-old infants are shown a sequence of events in which one object is added to another behind a screen, they expect to see two objects when the screen is removed (see **Figure 11.12**). And they exhibit surprise—in the form of longer looking—when their expectation is violated. This finding suggested that the infants understood that 1 + 1 = 2. Similar manipulations in subsequent studies suggested that infants also understand that 2 − 1 = 1, that 2 + 1 = 3, and that 3 − 1 = 2 (Hauser & Carey, 1998; Wynn, 1998). Thus, Wynn concluded that infants have a primitive "number sense." However, skeptics raised some questions about the interpretation of these surprising findings, which brings us to our Featured Study for this chapter.

FEATURED STUDY

Can Infants Do Arithmetic?

Critics of Wynn's previous research argued that alternative explanations could account for her findings. Specifically, they suggested that infants' surprise in response to incorrect numerical outcomes could reflect the operation of a simple object-tracking system rather than a capacity to work with numbers (Simon, 1997; Trick & Pylyshyn, 1994). According to this view, infants attempt to keep track of ob-

jects in their view; they look longer at incorrect outcomes because these outcomes produce a mismatch between the "object files" they stored in memory and the objects presented visually. In other words, their surprise does not mean that they are doing arithmetic. In the present study, McCrink and Wynn set out to conduct an experiment that might rule out this potentially plausible explanation for

earlier findings. They note that research on infants' object-tracking capabilities indicates that they are able to track only a maximum of four objects simultaneously. So, the object-tracking explanation is plausible when problems involve four or fewer elements, as in previous research, but it would not be a viable alternative explanation if earlier findings could be replicated with larger numbers. Thus, the present study tested the hypothesis that infants would look longer at wrong outcomes for the arithmetic operations of 5 + 5 and 10 − 5.

Method

Participants. The final sample consisted of twenty-six 9-month-old infants (13 males and 13 females) whose parents responded to recruitment efforts in the southeastern Connecticut area. Some additional infants were tested but had to be excluded because they were too fussy or uncooperative to complete the experiment. Half of the subjects were presented with an addition problem (5 + 5) and the other half were presented with a subtraction problem (10 − 5).

Procedure. The infants sat in a carseat in front of a computer monitor with a parent present, but the parent was facing away from the computer. The numerical scenarios were presented on the computer screen. A small curtain was lowered to block the infant's view of the computer at the end of each trial and raised to begin the next trial. A hidden observer monitored how long the infants looked when the final outcomes in the numerical sequences were revealed.

Materials. In the addition scenario, five rectangles were dropped into view and then moved to the right side of the screen where they were covered by a panel that rose up from the bottom. Then five more rectangles dropped into view and migrated behind the panel. Finally, the panel moved downward to reveal either 10 rectangles (the correct outcome) or only 5 rectangles (the incorrect outcome). In the subtraction scenario, 10 rectangles dropped into view and moved behind the panel. Then 5 rectangles moved out from behind the panel and migrated off the screen. Finally, the panel moved downward to reveal either 10 rectangles (the incorrect outcome) or 5 rectangles (the correct outcome).

Results

The infants who saw the addition operation looked longer at the wrong outcome (mean = 10.28 seconds) than right outcome (mean = 7.35 seconds). Likewise, the subjects who viewed the subtraction sequence looked at the
Figure 11.13

Mean looking time for correct and incorrect numerical operations. As predicted, 9-month-old infants shown correct and incorrect numerical operations looked longer at incorrect outcomes, suggesting that they were surprised by the wrong outcomes. (Data from McCrink & Wynn, 2004)

wrong outcome longer than the right outcome, although the difference was not as large as in the addition scenario (see **Figure 11.13**).

Discussion

The results suggest that 9-month-old infants have some understanding that 5 + 5 = 10 and that 10 − 5 = 5. Given the larger size of these numbers (in comparison to previous research), these results cannot be attributed to the operation of infants' object-tracking system. Hence, the authors conclude that the infants "were performing numerical computations." They also note that their findings support the idea that the human brain may have an innate ability to work with numbers.

Comment

This study was featured primarily because the results border on amazing. Prior to Wynn's breakthrough research in the 1990s, few scientists would have given any credence to the hypothesis that infants could understand mathematical operations that would make a kindergartner proud. The study also illustrates the typical ebb and flow of scientific progress, which often involves someone reporting an interesting finding, only to have its meaning challenged by a skeptic who suggests an alternative explanation, which leads to further research that pits the competing explanations against each other.
Karen Wynn

"Human infants are able to represent and reason about number. . . . humans possess a mental 'number mechanism,' designed through natural selection."

Again and again in recent years, research has shown that infants appear to understand surprisingly complex concepts that they have had virtually no opportunity to learn about. These findings have led some theorists to conclude that certain basic cognitive abilities are biologically built into humans'

neural architecture. The theorists who have reached this conclusion tend to fall into two camps: nativists and evolutionary theorists. The *nativists* simply assert that humans are prewired to readily understand certain concepts without making any assumptions about *why* humans are prewired in these ways

(Spelke & Kinzler, 2007; Spelke & Newport, 1998). Their principal interest is to sort out the complex matter of what is prewired and what isn't.

Evolutionary theorists agree with the nativists that humans are prewired for certain cognitive abilities, but they are keenly interested in *why.* As you might expect, they maintain that this wiring is a product of natural selection, and they strive to understand its adaptive significance (Hauser & Carey, 1998; Wynn, 1998). For example, evolutionary theorists are interested in how basic addition-subtraction abilities may have enhanced our hominid ancestors' success in hunting, foraging, and social bargaining. The evolutionary theorists also argue that the findings on infants' surprising abilities support their view that *the human mind is modular*—that it is made up of domain-specific modules that have been crafted by natural selection to solve specific adaptive problems, such as recognizing faces, discriminating simple speech sounds, and understanding basic properties of objects (Gelman & Williams, 1998; Leslie, 1994).

The Development of Moral Reasoning   9d

In Europe, a woman was near death from cancer. One drug might save her, a form of radium that a druggist in the same town had recently discovered. The druggist was charging $2,000, ten times what the drug cost him to make. The sick woman's husband, Heinz, went to everyone he knew to borrow the money, but he could only get together about half of what it cost. He told the druggist that his wife was dying and asked him to sell it cheaper or let him pay later. But the druggist said, "No." The husband got desperate and broke into the man's store to steal the drug for his wife. Should the husband have done that? Why? (Kohlberg, 1969, p. 379)

What's your answer to Heinz's dilemma? Would you have answered the same way three years ago? Can you guess what you might have said at age 6? By presenting similar dilemmas to participants and studying their responses, Lawrence Kohlberg (1976, 1984; Colby & Kohlberg, 1987) developed a model of *moral development.* What is morality? That's a complicated question that philosophers have debated for centuries. For our purposes, it will suffice to say that *morality* involves the ability to distinguish right from wrong and to behave accordingly.

Kohlberg's Stage Theory   9d

Kohlberg's model is the most influential of a number of competing theories that attempt to explain how youngsters develop a sense of right and wrong. His work was derived from much earlier work by Piaget (1932). Piaget theorized that moral development is determined by cognitive development. By this he meant that the way individuals think out moral issues depends on their level of cognitive development. This assumption provided the springboard for Kohlberg's research.

Kohlberg's theory focuses on moral *reasoning* rather than overt *behavior.* This point is best illustrated by describing Kohlberg's method of investigation. He presented his participants with thorny moral questions such as Heinz's dilemma, then asked the subjects what the actor in the dilemma should do, and more important, why. It was the *why* that interested Kohlberg. He examined the nature and progression of subjects' moral reasoning.

The result of this work is the stage theory of moral reasoning outlined in **Figure 11.14**. Kohlberg found that individuals progress through a series of three levels of moral development, each of which can be broken into two sublevels, yielding a total of six stages. Each stage represents a different approach to thinking about right and wrong.

Younger children at the *preconventional level* think in terms of external authority. Acts are wrong be-

Figure 11.14
Kohlberg's stage theory.
Kohlberg's model posits three levels of moral reasoning, each of which can be divided into two stages. This chart summarizes some of the key facets in how individuals think about right and wrong at each stage.

Stage 1	Stage 2	Stage 3	Stage 4	Stage 5	Stage 6
Punishment orientation	Naive reward orientation	Good boy/good girl orientation	Authority orientation	Social contract orientation	Individual principles and conscience orientation
Right and wrong is determined by what is punished.	Right and wrong is determined by what is rewarded.	Right and wrong is determined by close others' approval or disapproval.	Right and wrong is determined by society's rules, and laws, which should be obeyed rigidly.	Right and wrong is determined by society's rules, which are viewed as fallible rather than absolute.	Right and wrong is determined by abstract ethical principles that emphasize equity and justice.
Preconventional level		Conventional level		Postconventional level	

cause they are punished, or right because they lead to positive consequences. Older children who have reached the *conventional level* of moral reasoning see rules as necessary for maintaining social order. They therefore accept these rules as their own. They "internalize" these rules not to avoid punishment but to be virtuous and win approval from others. Moral thinking at this stage is relatively inflexible. Rules are viewed as absolute guidelines that should be enforced rigidly.

During adolescence, some youngsters move on to the *postconventional level,* which involves working out a personal code of ethics. Acceptance of rules is less rigid, and moral thinking shows some flexibility. Subjects at the postconventional level allow for the possibility that someone might not comply with some of society's rules if they conflict with personal ethics. For example, participants at this level might applaud a newspaper reporter who goes to jail rather than reveal a source of information who was promised anonymity.

Evaluating Kohlberg's Theory

How has Kohlberg's theory fared in research? The central ideas have received reasonable support. Progress in moral reasoning is indeed closely tied to cognitive development (Walker, 1988). Studies also show that youngsters generally do progress through Kohlberg's stages of moral reasoning in the order that he proposed (Walker, 1989). Furthermore, relations between age and level of moral reasoning are in the predicted directions (Rest, 1986). Repre-
Figure 11.15

Age and moral reasoning. The percentages of different types of moral judgments made by subjects at various ages are graphed here (based on Kohlberg, 1963, 1969). As predicted, preconventional reasoning declines as children mature, conventional reasoning increases during middle childhood, and postconventional reasoning begins to emerge during adolescence. But at each age, children display a mixture of various levels of moral reasoning.

sentative age trends are shown in **Figure 11.15**: As children get older, stage 1 and stage 2 reasoning declines, while stage 3 and stage 4 reasoning increases. However, there is great variation in the age at which individuals reach specific stages, and very few people reach stage 6, which raises doubts about its validity (Lapsley, 2006). Finally, evidence suggests that moral *reasoning* is predictive of moral *behavior,* although the association is disappointingly modest (Bruggerman & Hart, 1996). That is, youngsters who are at higher stages of moral development are somewhat more likely to be altruistic, conscientious, and honest than youngsters at lower stages (Fabes et al., 1999; Taylor & Walker, 1997). Although these

concept check 11.3

Analyzing Moral Reasoning

Check your understanding of Kohlberg's theory of moral development by analyzing hypothetical responses to the following moral dilemma.

A midwest biologist has conducted numerous studies demonstrating that simple organisms such as worms and paramecia can learn through conditioning. It occurs to her that perhaps she could condition fertilized human ova, to provide a dramatic demonstration that abortions destroy adaptable, living human organisms. This possibility appeals to her, as she is ardently opposed to abortion. However, there is no way to conduct the necessary research on human ova without sacrificing the lives of potential human beings. She desperately wants to conduct the research, but obviously, the sacrifice of human ova is fundamentally incompatible with her belief in the sanctity of human life. What should she do? Why? [Submitted by a student (age 13) to Professor Barbara Banas at Monroe Community College]

In the spaces on the left of each numbered response, indicate the level of moral reasoning shown, choosing from the following: (a) preconventional level, (b) conventional level, or (c) postconventional level. The answers are in Appendix A.

_____ **1.** She should do the research. Although it's wrong to kill, there's a greater good that can be realized through the research.

_____ **2.** She shouldn't do the research because people will think that she's a hypocrite and condemn her.

_____ **3.** She should do the research because she may become rich and famous as a result.
findings support the utility of Kohlberg's model, like all influential theorists, he has his critics. They have raised the following issues:

1. It's not unusual to find that a person shows signs of several adjacent levels of moral reasoning at a particular point in development (Walker & Taylor, 1991). As we noted in the critique of Piaget, this mixing of stages is a problem for virtually all stage theories.

2. Evidence is mounting that Kohlberg's dilemmas may not be valid indicators of moral development in some cultures (Nucci, 2002). Some critics believe that the value judgments built into Kohlberg's theory reflect a liberal, individualistic ideology characteristic of modern Western nations that is

much more culture-specific than Kohlberg appreciated (Miller, 2006).

3. A consensus is building that Kohlberg's theory led to a constricted focus on reasoning about interpersonal conflicts while ignoring many other important aspects of moral development (Walker, 2007). Thus, contemporary researchers are increasingly turning their attention to other dimensions of moral development, including the development of empathy (Eisenberg, Spinrad, & Sadovsky, 2006), the emergence of conscience (Grusec, 2006), the development of prosocial (helping, sharing) behavior (Carlo, 2006), and the significance of moral emotions (such as shame and guilt) (Tangney, Stuewig, & Mashek, 2007).

REVIEW of Key Learning Goals

11.3 Motor development follows cephalocaudal (head-to-foot) and proximodistal (center-outward) trends. Early motor development depends on both maturation and learning. Developmental norms for motor skills and other types of development are only group averages. Cultural variations in the pacing of motor development demonstrate the importance of learning.

11.4 In a longitudinal study, Thomas and Chess found that most infants could be classified as easy, slow-to-warm-up, or difficult children during the first few months of life. Kagan's research suggests that variations in inhibited-uninhibited temperament are fairly stable and have a genetic basis. Infant temperament may lay the foundation for adult personality.

11.5 Harlow's work with monkeys undermined the reinforcement explanation of attachment. Bowlby proposed an evolutionary explanation that has been very influential. Infant-mother attachments fall into four categories: secure, anxious-ambivalent, avoidant, and disorganized-disoriented. Research shows that attachment emerges out of an interplay between infant and mother. A secure attachment fosters self-esteem, persistence, curiosity, and self-reliance, among other desirable traits.

11.6 Some studies suggest that extensive dependence on day care might disrupt the attachment process. But the negative effects of day care appear to be small and inconsistent, while high-quality day care is associated with some positive effects. Cultural variations in childrearing can affect the patterns of attachment seen in a society, but secure attachment is predominant around the world.

11.7 Like other stage theories, Erikson's theory of personality development proposes that individuals evolve through a series of stages over the life span. In each of the eight stages the person wrestles with two opposing tendencies evoked by that stage's psychosocial crisis.

11.8 According to Piaget's theory of cognitive development, the key advance during the sensorimotor period is the child's gradual recognition of the permanence of objects. The preoperational period is marked by certain deficiencies in thinking—notably, centration, irreversibility, and egocentrism. During the concrete operations period, children develop the ability to perform operations on mental representations. The stage of formal operations ushers in more abstract, systematic, and logical thought. Piaget may have underestimated some aspects of children's cognitive development, and his theory, like other stage theories, does not explain individual differences very well.

11.9 Vygotsky's sociocultural theory maintains that children's cognitive development is fueled by social interactions with parents and others and that culture influences how cognitive growth unfolds. Recent research has shown that infants appear to understand surprisingly complex concepts that they have had virtually no opportunity to learn about. For example, the Featured Study showed that infants can add and subtract small numbers. Findings such as these have led some theorists to conclude that basic cognitive abilities are biologically built into humans' neural architecture.

11.10 According to Kohlberg, moral reasoning progresses through six stages that are related to age and determined by cognitive development. Age-related progress in moral reasoning has been found in research, although a great deal of overlap occurs between adjacent stages, and Kohlberg's theory is more culture-specific than he realized.

The Transition of Adolescence

Adolescence is a transitional period between childhood and adulthood. Its age boundaries are not exact, but in our society adolescence is thought to begin around age 13 and end at about age 21–22. Although most contemporary societies have at least a brief period of adolescence, it has *not* been universal historically or across cultures (Larson & Wilson, 2004; Schlegel & Barry, 1991). In some societies, young people used to move directly from childhood to adulthood. A protracted period of adolescence emerged in conjunction with industrialization. In modern societies, rapid technological progress made lengthy education, and therefore prolonged economic dependence, the norm. Thus, in our own culture, middle school, high school, and college students often have a "marginal" status. They become physiologically mature and capable of reproduction. Yet they have not achieved the emotional and economic independence from their parents that are the hallmarks of adulthood. Let's begin our discussion of adolescent development with its most visible aspect: the physical changes that transform the body of a child into that of an adult.

Physiological Changes

Recall for a moment your junior high school days. Didn't it seem that your body grew so fast about this time that your clothes just couldn't "keep up"? This phase of rapid growth in height and weight is called the *adolescent growth spurt.* Brought on by hormonal changes, it typically starts at about 10 years of age in girls and about two years later in boys (Archibald, Graber, & Brooks-Dunn, 2003). Scientists are not sure about what triggers the hormonal changes that underlie the adolescent growth spurt, but evidence suggests that rising levels of *leptin,* the recently discovered hormone that reflects the body's fat cell storage (see Chapter 10), may play a role (Shalitin & Phillip, 2003).

The term **pubescence is used to describe the two-year span preceding puberty during which the changes leading to physical and sexual maturity take place.** In addition to growing taller and heavier during pubescence, children begin to develop the physical features that characterize adults of their respective sexes. These features are termed **secondary sex characteristics—physical features that distinguish one sex from the other but that are not essential for reproduction.** For example, males go through a voice change, develop facial hair, and experience greater skeletal and muscle growth in the upper torso, leading to broader shoulders (see **Figure 11.16**). Females experience breast growth and a widening of the pelvic bones plus increased fat deposits in this area, resulting in wider hips (Susman & Rogol, 2004).

Note, however, that the capacity to reproduce is not attained in pubescence. This comes later.
Figure 11.16

Physical development at puberty. Hormonal changes during puberty lead not only to a growth spurt but also to the development of secondary sex characteristics. The pituitary gland sends signals to the adrenal glands and gonads (ovaries and testes), which secrete hormones responsible for various physical changes that differentiate males and females.

Puberty is the stage during which sexual functions reach maturity, which marks the beginning of adolescence. It is during puberty that the *primary sex characteristics—the structures necessary for reproduction*—develop fully. In the male these include the testes, penis, and related internal structures. In the female they include the ovaries, vagina, uterus, and other internal structures.

In females, the onset of puberty is typically signaled by *menarche—the first occurrence of menstruation,* which reflects the culmination of a series of hormonal changes (Pinyerd & Zipf, 2005). American girls typically reach menarche at ages 12–13, with further sexual maturation continuing until approximately age 16 (Susman, Dorn, & Schiefelbein, 2003). American boys typically experience *spermarche—the first occurrence of ejaculation,* at ages 13–14, with further sexual maturation continuing until approximately 18 (Archibald et al., 2003).

Interestingly, *generational* changes have occurred in the timing of puberty over the last 150 years. Today's adolescents begin puberty at a younger age, and complete it more rapidly, than their counterparts in earlier generations (Bellis, Downing, & Ashton, 2006). This trend appears to be occurring in both sexes, although more precise data are available for females, as the marker for puberty (menarche) is more readily apparent in females (Herman-Giddens, 2006). The reasons for this trend are the subject of debate, but it seems likely that a multiplicity of factors have contributed (Archibald et al., 2003; Bellis et al. 2006). The most obvious potential causes are widespread improvements in nutrition and medical care, which would probably explain why the trend toward younger puberty has been limited to modern, "developed" countries. The earlier onset of puberty may also be attributable to increases in family-related stress. Evolutionary theorists have hypothesized that humans have been programmed by natural selection to respond to insensitive parenting (rejection, family discord, father absence) with accelerated sexual maturation (Belsky, 1999; Ellis, 2004). Research on individual variations in the onset of puberty has supported this hypothesis for females (Belsky, 2007). So, increases in family stress and instability over the last century may be a contributing factor to generational changes in the onset of puberty.

The timing of puberty varies from one adolescent to the next over a range of about 5 years (ages 10–15 for girls, 11–16 for boys). Generally, *girls who mature early and boys who mature late seem to experience more subjective distress and emotional difficulty with the transition to adolescence* (Susman et al., 2003). However, in both males and females, early maturation is associated with greater use of alcohol and drugs, more

The timing of sexual maturation can have important implications for adolescents. Youngsters who mature unusually early or unusually late often feel uneasy about this transition.

high-risk behavior, greater aggression, and more delinquency (Lynne et al., 2007; Steinberg & Morris, 2001). Among females, early maturation is also correlated with earlier experience of intercourse, more unwanted pregnancies, a greater risk for eating problems, and a variety of psychological disorders (Archibald et al., 2003). Thus, we might speculate that early maturation often thrusts both sexes (but especially females) toward the adult world too soon.

Neural Development

Recent years have brought significant advances in the study of adolescents' neural development (Geidd, 2008; McAnarney, 2008). The size of the human brain does not increase significantly after age 5 (Durston et al., 2001). Given this fact, it was widely assumed until recently that the brain did not undergo much development after middle childhood. However, the increased availability of MRI scans, which can provide exquisitely detailed images of the brain, has permitted neuroscientists to conduct entirely new investigations of whether there are age-related changes in brain structure. These studies have uncovered some interesting developmental trends during adolescence. For example, the volume of white matter in the brain grows throughout adolescence (Schmithorst et al., 2002). This means that *neurons are becoming more myelinated* (see Chapter 3), which presumably leads to enhanced conductivity and connectivity in the brain. In contrast, gray mat-
ZITS

ter decreases in volume (Toga, Thompson, & Sowell, 2006). This finding is thought to reflect the process of *synaptic pruning*—the elimination of less-active synapses—which plays a key role in the formation of neural networks (see Chapter 3).

Perhaps the most interesting discovery about the adolescent brain has been that increased myelinization and synaptic pruning are most pronounced in the *prefrontal cortex* (see **Figure 11.17**; Keating, 2004). Thus, *the prefrontal cortex appears to be the last area of the brain to fully mature,* and this maturation may not be complete until one's mid-20s (Gogtay et al., 2004). Much has been made of this finding, because the prefrontal cortex has been characterized as an "executive control center" that is crucial to high-level cognitive functions, such as planning, organizing, emotional regulation, and response inhibition (Nelson et al., 2002). Theorists have suggested that the immaturity of the prefrontal cortex may explain why risky behavior (such as reckless driving, experimentation with drugs, dangerous stunts, binge drinking, unprotected sex, and so forth) peaks during adolescence (Compas, 2004; Dahl, 2003).

That said, Kuhn (2006) notes that media pundits have gotten carried away, blaming the immaturity of the adolescent prefrontal cortex for "just about everything about teens that adults have found perplexing" (p. 59). Other factors also contribute to risky behavior during adolescence. One of these factors is susceptibility to peer influence (Steinberg, 2007). Adolescents spend a great deal of time with their peers. One elegant laboratory study found that the presence of peers more than doubled the number of risks taken by teenagers in a video game involving in-the-moment decisions about crash risks (Gardner & Steinberg, 2005). In contrast, older adults' risk taking was not elevated by the presence of peers (see **Figure 11.18**).

Figure 11.17

The prefrontal cortex. Recent research suggests that neural development continues throughout adolescence. Moreover, the chief site for much of this development is the prefrontal cortex, which appears to be the last area of the brain to mature fully. This discovery may have fascinating implications for understanding the adolescent brain, as the prefrontal cortex appears to play a key role in emotional regulation and self-control.

Figure 11.18

Peer influence on risk taking. Gardner and Steinberg (2005) had adolescents, young adults, and adults play a video game involving simulated driving in which participants had to make quick decisions about crash risks. The dependent variable, which indexed subjects' risk taking, was the number of crashes experienced. Some participants played the video game alone, whereas others played in the presence of peers. The data showed that the presence of peers increased risk taking by young adults moderately and by adolescents considerably, but adults' risk taking was unaffected. These findings suggest that susceptibility to peer influence may increase risky behavior among adolescents and young adults.

Time of Turmoil?

Back around the beginning of the 20th century, G. Stanley Hall (1904), one of psychology's great pioneers (see Chapter 1), proposed that the adolescent years are characterized by convulsive instability and disturbing inner turmoil. Hall attributed this turmoil to adolescents' erratic physical changes and resultant confusion about self-image. Over the decades, many theorists have agreed with Hall's characterization of adolescence as a stormy period.

Statistics on *adolescent suicide* would seem to support the idea that adolescence is a time marked by turmoil, but the figures can be interpreted in various ways. On the one hand, suicide rates among adolescents have risen alarmingly in recent decades. On the other hand, even with this steep increase, suicide rates for adolescents are a little lower than those for older age groups (Sudak, 2005; see **Figure 11.19**). Actually, the suicide crisis among teenagers involves *attempted* suicide more than *completed* suicide. It is difficult to compile accurate data on suicide attempts (which are often covered up), but experts estimate that when all age groups are lumped together, suicide attempts outnumber actual suicidal deaths by as much as 20 to 1 (Sudak, 2005). However, this ratio of attempted to completed suicides is much higher for adolescents and is estimated to range anywhere from 100:1 to 200:1 (Maris, Berman, & Silverman, 2000). Thus, attempted suicide is a major issue during adolescence. About 2% of adolescent males and about 5% of adolescent females attempt suicide each year in the United States (Blum & Rinehart, 2000). Although adolescent girls *attempt* suicide more often than adolescent boys, completed suicide rates are almost six times higher for boys (Serocynski, Jacquez, & Cole, 2003).

Returning to our original question, does the weight of evidence support the idea that adolescence is usually a period of turmoil and turbulence? Over-all, the consensus of the experts seems to be that adolescence is *not* an exceptionally difficult period (Petersen et al., 1993; Steinberg & Levine, 1997). However, in an influential reanalysis of the evidence, Jeffrey Arnett (1999) has argued convincingly that "not all adolescents experience storm and stress, but storm and stress is more likely during adolescence than at other ages" (p. 317). Arnett supports his intermediate position by summarizing research on adolescents' moods, risky behaviors, and conflicts with their parents. Research shows that adolescents do experience more volatile and more negative emotions than their parents or younger children do (Rosenblum & Lewis, 2003). Studies also show that various types of risky behavior, such as substance abuse, careless sexual practices, and dangerous driving, peak during late adolescence (Perkins & Borden, 2003). Finally, adolescence *does* bring an increase in parent-child conflicts (Granic, Dishion, & Hollenstein, 2003). Arnett is quick to emphasize that turmoil in adolescence is far from universal, but he maintains that, on the average, adolescence is somewhat more stressful than other developmental periods.

Although turbulence and turmoil are not *universal* features of adolescence, challenging adaptations *do* have to be made during this period. In particular, most adolescents struggle to some extent in their effort to achieve a sound sense of identity.

The Search for Identity

Erik Erikson was especially interested in personality development during adolescence, which is the fifth of the eight major life stages he described (consult **Figure 11.8** on page 452). According to Erikson (1968), the premier challenge of adolescence is the struggle to form a clear sense of identity. This struggle involves working out a stable concept of oneself as a unique individual and embracing an ideology

Figure 11.19

Suicide rates by age. Although suicide rates for adolescents have increased dramatically in recent decades, the suicide rates for this age group remain lower than the suicide rates for all older age groups.

Source: Centers for Disease Control and Prevention, *Health United States,* 2005.
or system of values that provides a sense of direction. In Erikson's view, adolescents grapple with questions such as "Who am I, and where am I going in life?"

Erikson recognized that the process of identity formation often extends beyond adolescence, as his own life illustrates (Coles, 1970; Roazen, 1976). During adolescence Erikson began to resist family pressures to study medicine. Instead, he wandered about Europe until he was 25, trying to "find himself" as an artist. His interest in psychoanalysis was sparked by an introduction to Sigmund Freud's youngest daughter, Anna, a pioneer of child psychoanalysis. After his psychoanalytic training, he moved to the United States. When he became a naturalized citizen in 1939, he changed his surname from Homburger to Erikson. Clearly, Erikson was struggling with the question of "Who am I?" well into adulthood. Small wonder, then, that he focused a great deal of attention on identity formation.

Although the struggle for a sense of identity can be a lifelong process, it does tend to be especially intense during adolescence. Adolescents deal with identity formation in a variety of ways. According to James Marcia (1966, 1980, 1994), the presence or absence of a sense of commitment (to life goals and values) and a sense of crisis (active questioning and exploration) can combine to produce four different *identity statuses* (see **Figure 11.20**). These are not stages that people pass through, but orientations that may occur at a particular time. In order of increasing maturity, Marcia's four identity statuses begin with *identity diffusion,* a state of rudderless apathy, with no commitment to an ideology. *Identity foreclosure* is a premature commitment to visions, values, and roles—typically those prescribed by one's parents. Foreclosure is associated with conformity and not being very open to new experiences (Kroger, 2003). An *identity moratorium* involves delaying commitment for a while to experiment with alternative ideologies and careers. *Identity achievement* involves arriving at a sense of self and direction after some consideration of alternative possibilities. Identity achievement is associated with higher self-esteem, conscientiousness, security, achievement motivation, and capacity for intimacy (Kroger, 2003).

Research has revealed that a sizable majority of adolescents shift back and forth among the four identity statuses (Berzonsky & Adams, 1999). Moreover, people tend to reach identity achievement at later ages than originally envisioned by Marcia. By late adolescence, only a small minority of individuals have reached identity achievement, so the struggle for a sense of identity routinely extends into young adulthood.

	Crisis	
	Present	**Absent**
Commitment — **Present**	**Identity achievement** (successful achievement of a sense of identity)	**Identity foreclosure** (unquestioning adoption of parental or societal values)
Commitment — **Absent**	**Identity moratorium** (active struggling for a sense of identity)	**Identity diffusion** (absence of struggle for identity, with no obvious concern about it)

Figure 11.20

Marcia's four identity statuses. According to Marcia (1980), the occurrence of identity crisis and exploration and the development of personal commitments can combine into four possible identity statuses, as shown in this diagram. The progressively darker shades of blue signify progressively more mature identity statuses.

Emerging Adulthood as a New Developmental Stage

The finding that the search for identity routinely extends into adulthood is one of many considerations that have led Jeffrey Arnett to make the radical claim that we ought to recognize the existence of a new developmental stage in modern societies, which he has christened *emerging adulthood.* According to Arnett (2000, 2004, 2006), the years between age 18 and 25 (roughly) have become a distinct, new transitional stage of life. He attributes the rise of this new developmental period to a variety of demographic trends, such as more people delaying marriage and parenthood until their late 20s or early 30s, lengthier participation in higher education, increased barriers to financial independence, and so forth. "What is different today," he says, "is that experiencing the period from the late teens through the mid-20s as a time of exploration and instability is now the norm" (Arnett, 2006, p. 4).

Arnett (2000, 2006) maintains that emerging adulthood is characterized by a number of prominent features. A central feature is the subjective feeling that one is in between adolescence and adulthood. When 18–25-year-olds are asked "Do you feel like you have reached adulthood?" the modal response is "Yes and no" (see **Figure 11.21** on the next page). They don't feel like adolescents, but most don't see themselves as adults either. Another feature of emerging adulthood is that it is an age of possibilities. It tends to be a time of great optimism about one's personal future. A third aspect of emerging adulthood is that it is a self-focused time of life. People in this period tend to be unfettered by duties, commitments, and social obligations, which gives them unusual autonomy and freedom to explore new options. Finally, Arnett has found that to a surprising degree emerging adulthood is a period of identity formation. Although the search for identity has traditionally been viewed as

"Do you feel like you have reached adulthood?"   ■ Yes   ■ Yes and no   ■ No

Figure 11.21

Emerging adulthood as a phase in between adolescence and adulthood. Arnett (2006) characterizes emerging adulthood as an "age of feeling in-between." This characterization comes from a study (2001) in which he asked participants of various ages "Do you feel like you have reached adulthood?" As you can see in the data shown here, the dominant response in the 18–25 age group was an ambivalent "Yes and no," but it shifted to predominantly "Yes" in the 26–35 age group.

theory has already inspired a good deal of research on the dynamics and developmental significance of emerging adulthood (Acquilino, 2006; Cote, 2006; Labouvie-Vief, 2006; Tanner, 2006). This research needs to determine whether emerging adulthood really represents a new stage of development or a historical curiosity associated with recent decades.

an adolescent phenomenon, Arnett's research indicates that identity formation continues to be a crucial issue for most young adults. Arnett's provocative

The Expanse of Adulthood

The concept of development was once associated almost exclusively with childhood and adolescence, but today development is widely recognized as a lifelong journey. Interestingly, patterns of development during the adult years are becoming increasingly diverse. The boundaries between young, middle, and late adulthood are becoming blurred as more and more people have children later than one is "supposed" to, retire earlier than one is "supposed" to, and so forth. In the upcoming pages we will look at some of the major developmental transitions in adult life, but you should bear in mind that in adulthood (even more so than childhood or adolescence) there are many divergent pathways and timetables.

Personality Development   9b

In recent years, research on adult personality development has been dominated by one key question: How stable is personality over the life span? We'll look at this issue and Erikson's view of adulthood in our discussion of personality development in the adult years.

The Question of Stability

How common are significant personality changes in adulthood? Is a grouchy 20-year-old going to be a grouchy 40-year-old and a grouchy 65-year-old? Or can the grouchy young adult become a mel-

low senior citizen? After tracking subjects through adulthood, many researchers have been impressed by the amount of change observed (Helson, Jones, & Kwan, 2002; Whitbourne et al., 2002). For example, Roger Gould (1975) concluded that "the evolution of a personality continues through the fifth decade of life." In contrast, many other researchers have concluded that personality tends to be quite stable over periods of 20 to 40 years (Caspi & Herbener, 1990; Costa & McCrae, 1994, 1997). A review of 150 relevant studies, involving almost 50,000 participants, concluded that personality in early adulthood is a good predictor of personality in late adulthood and that the stability of personality increases with age up to about age 50 (Roberts & DelVecchio, 2000).

Clearly, researchers assessing the stability of personality in adulthood have reached very different conclusions. How can these contradictory conclusions be reconciled? It appears that *both* conclusions are accurate—they just reflect different ways of looking at the data (Bertrand & Lachman, 2003). Recall from Chapter 9 that psychological test scores are *relative* measures—they show how one scores *relative to other people.* Raw scores are converted into *percentile scores* that indicate the precise degree to which one is above or below average on a particular trait. The data indicate that these percentile scores tend to be remarkably stable over lengthy spans of time—people's relative standing doesn't tend to change much.

However, if we examine participants' raw scores, we can see meaningful developmental trends. For example, adults' mean raw scores on extraversion, neuroticism, and openness to experience tend to decline moderately with increasing age, while measures of agreeableness and conscientiousness tend to increase (Bertrand & Lachman, 2003; Caspi, Roberts, & Shiner, 2005; see **Figure 11.22**).

A recent meta-analysis of 92 studies found statistically significant change over the course of the adult years in 75% of the personality traits studied (Roberts, Walton, & Viechtbauer, 2006). The bulk of this change appears to occur between the ages of 20 and 40, but substantial changes continue into old age on some traits (Roberts & Mroczek, 2008). The trends seen could be characterized as positive changes, in that aging seems to bring increased warmth, self-confidence, self-control, and emotional stability (Roberts & Wood, 2006). Moreover, the people who exhibit these trends at the youngest ages tend to lead healthier and longer lives (Roberts et al., 2007). In sum, it appears that personality in adulthood is characterized by *both* stability and change.

Figure 11.22
Examples of personality trends in the adult years. According to Brent Roberts and Daniel Mroczek (2008), when researchers examine participants' mean raw scores on personality measures, they find meaningful trends over the decades of adulthood. The trends for two specific traits—agreeableness and conscientiousness—are shown here as examples. Using subjects' test scores in adolescence as a baseline, you can see how measures of agreeableness and conscientiousness increase substantially over the decades.

Erikson's View of Adulthood

Insofar as personality changes during the adult years, Erik Erikson's (1963) theory offers some clues about the nature of changes people can expect. In his eight-stage model of development over the life span, Erikson divided adulthood into three stages (see again **Figure 11.8**). In the *early adulthood* stage called *intimacy versus isolation,* the key concern is whether one can develop the capacity to share intimacy with others. Successful resolution of the challenges in this stage should promote empathy and openness. In *middle adulthood,* the psychosocial crisis pits *generativity versus self-absorption.* The key challenge is to acquire a genuine concern for the welfare of future generations, which results in providing unselfish guidance to younger people and concern with one's legacy. During the *late adulthood* stage called *integrity versus despair,* the challenge is to avoid the tendency to dwell on the mistakes of the past and on one's imminent death. People need to find meaning and satisfaction in their lives, rather than wallow in bitterness and resentment. Empirical research on the adult stages in Erikson's theory has been sparse, but generally supportive of the theory. For example, researchers have found that generativity increases between young adulthood and middle age, as Erikson's theory predicts (de St. Aubin, McAdams, & Kim, 2004; Stewart, Ostrove, & Helson, 2001).

Transitions in Family Life

Many of the important transitions in adulthood involve changes in family responsibilities and relationships. Nearly everyone emerges from a family, and most people go on to form their own families. However, the transitional period during which young adults are "between families" until they form a new family is being prolonged by more and more people.

Figure 11.23

Median age at first marriage. The median age at which people in the United States marry for the first time has been creeping up for both males and females since the mid-1960s. This trend indicates that more people are postponing marriage. (Data from the U.S. Bureau of the Census, 2007)

The percentage of young adults who are postponing marriage until their late twenties or early thirties has risen dramatically (see **Figure 11.23**). This trend is probably the result of a number of factors. Chief among them are the availability of new career options for women, increased educational requirements in the world of work, and increased emphasis on personal autonomy. Remaining single is a much more acceptable option today than it was a few decades ago (DeFrain & Olson, 1999). Nonetheless, over 90% of adults in the U.S. eventually marry.

Adjusting to Marriage

The newly married couple usually settle into their roles as husband and wife gradually. Difficulties with this transition are more likely when spouses come into a marriage with different expectations about marital roles. Unfortunately, substantial differences in role expectations seem particularly likely in this era of transition in gender roles (Brewster & Padavic, 2000). Most new couples are pretty happy, but 8%–14% of newlyweds score in the distressed range on measures of marital satisfaction, with the most commonly reported problems being difficulties balancing work and marriage and financial concerns (Schramm et al., 2005).

Women may be especially vulnerable to ambivalence about shifting marital roles. More and more women are aspiring to demanding careers, yet research shows that husbands' careers continue to take priority over their wives' vocational ambitions

(Haas, 1999). Moreover, many husbands maintain traditional role expectations about housework, child care, and decision making. Men's contribution to housework has increased noticeably since the 1960s, as you can see in **Figure 11.24**. However, studies indicate that wives are still doing the bulk of the household chores in America, even when they work outside the home (Bianchi et al., 2000; Sayer, 2005). Although married women perform about two-thirds of all housework, only about one-third of wives characterize their division of labor as unfair, because most women don't expect a 50-50 split (Coltrane, 2001). Women who have nontraditional attitudes about gender roles are more likely to perceive their share of housework as unfair than women with traditional attitudes (Coltrane, 2001). In contrast, couples in which the husband holds egalitarian attitudes have higher levels of martial happiness than those where the husband holds more traditional attitudes (Kaufman & Taniguchi, 2006).

The prechildren phase of the family life cycle used to be rather short for most newly married couples. Traditionally, couples just *assumed* that they would proceed to have children. In recent decades, however, ambivalence about the prospect of having children has clearly increased (Koropeckyj-Cox & Pendell, 2007), and the percentage of childless couples has doubled since 1960 (Bulcroft & Teachman, 2004). Hence, more and more couples are finding themselves struggling to decide *whether* to have children. Interestingly, in-
Figure 11.24

Housework trends since the 1960s. As these data show, the housework gap between husbands and wives has narrowed since the 1960s. Married men have more than doubled their housework, but it is the large reduction in wives' housework that has really shrunk the housework gap. (Data from Bianchi et al., 2000)

tentions about having children are not as stable over time as one might expect. In one study that followed adult participants over a span of six years, about one-quarter of the respondents changed their plans (Heaton, Jacobson, & Holland, 1999). These subjects were almost evenly split between those who planned to remain childless but subsequently decided they wanted to have children and those who intended to have children but subsequently expressed a preference for remaining child-free.

Adjusting to Parenthood

Although an increasing number of people are choosing to remain childless, the vast majority of married couples continue to have children. Most couples are happy with their decision to have children, but the arrival of the first child represents a major transition, and the disruption of routines can be emotionally draining (Bost et al., 2002). The transition to parenthood tends to have more impact on mothers than fathers (Nomaguchi & Milkie, 2003). New mothers, already physically exhausted by the birth process, are particularly prone to postpartum distress, and about 10%–13% experience depression within the first 12 weeks after birth (Dennis & Ross, 2005; Formichelli, 2001). The transition is more difficult when a wife's expectations regarding how much the father will be involved in child care are not met (Fox, Bruce, & Combs-Orme, 2000). A review of decades of research on parenthood and marital satisfaction, found that (1) parents exhibit lower marital satisfaction than comparable nonparents, (2) mothers of infants report the steepest decline in marital satisfaction, and (3) the more children couples have, the lower their marital satisfaction tends to be (Twenge, Campbell, & Foster, 2003).

Crisis during the transition to first parenthood is far from universal, however (Cox et al., 1999). Couples who have high levels of affection and commitment prior to the first child's birth are likely to maintain a stable level of satisfaction after the birth (Shapiro, Gottman, & Carrère, 2000). The key to making this transition less stressful may be to have *realistic expectations* about parental responsibilities (Belsky & Kelly, 1994). Studies find that stress is greatest in new parents who have overestimated the benefits and underestimated the costs of their new role. Interestingly, the nature of parenthood appears to be undergoing a cultural transition. Parents in more recent age cohorts tend to be more involved with and accessible to their children than previous generations (Parke, 2004).

As children grow up, parental influence over them tends to decline, and the early years of parenting—

that once seemed so difficult—are often recalled with fondness. When youngsters reach adolescence and seek to establish their own identities, gradual realignments occur in parent-child relationships. On the one hand, these relations generally are not as bitter or contentious as widely assumed (Laursen, Coy, & Collins, 1998). On the other hand, adolescents do spend less time in family activities, and their closeness to their parents declines while conflicts become more frequent (Smetana, Campione-Barr, & Metzger, 2006). The conflicts tend to involve everyday matters (chores and appearance) more than substantive issues (sex and drugs) (Collins & Laursen, 2006). When conflicts occur, they seem to have more adverse effects on the parents than the children. Ironically, although research has shown that adolescence is not as turbulent or difficult for youngsters as once believed, their parents *are* stressed out (Steinberg, 2001).

Adjusting to the Empty Nest

When parents get all their children launched into the adult world, they find themselves faced with an "empty nest." This period was formerly thought to be a difficult transition for many parents, especially mothers who were familiar only with the maternal role. In recent decades, however, more women have experience with other roles outside the home. Hence, evidence suggests that most parents adjust effectively to the empty nest transition and are more likely to have problems if their children *return* to the once-empty nest (Blacker, 1999; Dennerstein, Dudley, & Guthrie, 2002). Interestingly, one study found that the empty nest transition was tougher for fathers than mothers because fathers were less prepared for the change (Hagen & DeVries, 2004).

Aging and Physiological Changes

People obviously experience many physical changes as they progress through adulthood. In both sexes, hair tends to thin out and become gray, and many males confront receding hairlines and baldness. To the dismay of many, the proportion of body fat tends to increase with age, while the amount of muscle tissue decreases. Overall, weight tends to increase in most adults through the mid-50s, when a gradual decline may begin. These changes have little functional significance, but in our youth-oriented society, they often have a negative impact on self-concept, leading many people to view themselves as less attractive (Aldwin & Gilmer, 2004).

In the sensory domain, the key developmental changes occur in vision and hearing. The proportion

of people with 20/20 visual acuity declines with age, while farsightedness and difficulty seeing in low illumination become more common (Schieber, 2006). Sensitivity to color and contrast is also reduced (Fozard & Gordon-Salant, 2001). Hearing sensitivity begins declining gradually in early adulthood but usually isn't noticeable until after age 50. Hearing loss tends to be greater in men than in women and for high-frequency sounds more than low-frequency sounds (Yost, 2000). Even mild hearing loss can undermine speech perception and put an added burden on cognitive processing (Wingfield, Tun, & McCoy, 2005). These sensory losses would be more problematic, but in modern society they can usually be partially compensated for with eyeglasses, contacts, and hearing aids.

Age-related changes also occur in hormonal functioning during adulthood. Among women, these changes lead to *menopause.* This ending of menstrual periods, accompanied by a loss of fertility, typically occurs at around age 50 (Grady, 2006). Most women experience at least some unpleasant symptoms, such as hot flashes, headaches, night sweats, mood changes, sleep difficulties, and reduced sex drive, but the amount of discomfort varies considerably (Grady, 2006; Williams et al., 2007). Menopause is also accompanied by an elevated vulnerability to depression (Deecher et al., 2008). Not long ago, menopause was thought to be almost universally accompanied by severe emotional strain. However, it is now clear that most women experience relatively modest psychological distress (George, 2002; Walter, 2000).

Although people sometimes talk about "male menopause," men don't really go through an equivalent experience. Starting in middle age, testosterone levels *do* decline substantially (Bain, 2007; Morley & Perry, 2003), but these decreases are gradual rather than abrupt, and they are not associated with the onset of a constellation of symptoms comparable to what women experience (Jacobs, 2001; Wald, Miner, & Seftel, 2008). That said, the effects of declining testosterone levels in aging men *do* have functional significance (Hollander & Samons, 2003). Reduced testosterone is thought to contribute to age-related declines in muscle mass, sexual functioning, and mental sharpness (Bain, 2007). In light of such findings, physicians are increasingly providing testosterone supplementation to reduce these effects (Smith, 2003; Wald et al., 2008).

Aging and Neural Changes

The amount of brain tissue and the brain's weight decline gradually in late adulthood, mostly after age 60 (Victoroff, 2005). These trends appear to reflect both a decrease in the number of active neurons in some areas of the brain and shrinkage of still-active neurons, with neuron loss perhaps being less important than once believed (Albert & Killiany, 2001). Although this gradual loss of brain tissue sounds alarming, it is a normal part of the aging process. Its functional significance is the subject of some debate, but it doesn't appear to be a key factor in any of the age-related dementias. **A *dementia* is an abnormal condition marked by multiple cognitive deficits that include memory impairment.** Dementia can be caused by quite a variety of diseases, such as Alzheimer's disease, Parkinson's disease, Huntington's disease, and AIDS, to name just a few (Caine & Lyness, 2000). Because many of these diseases are more prevalent in older adults, dementia is seen in about 15%–20% of people over age 75 (Wise, Gray, & Seltzer, 1999). However, it is important to emphasize that dementia and "senility" are not part of the normal aging process. As Cavanaugh (1993) notes, "The term *senility* has no valid medical or psychological meaning, and its continued use simply perpetuates the myth that drastic mental decline is a product of normal aging" (p. 85).

Alzheimer's disease accounts for roughly 60% of all cases of dementia (Small, 2005). The estimated prevalence of Alzheimer's disease is 1% for ages 65–74, 8% for ages 80–85, and 20% for those over 90 (Hybels & Blazer, 2005). Alzheimer's disease is accompanied by major structural deterioration in the brain. Alzheimer's patients exhibit profound and widespread loss of neurons and brain tissue and the accumulation of characteristic neural abnormalities known as neuritic plaques and neurofibrillary tangles (Haroutunian & Davis, 2003). In the early stages of the disease, this damage is largely centered in the hippocampal region, which is known to play a crucial role in many facets of memory, but as the disease advances it spreads throughout much of the brain (Bourgeois, Seaman, & Servis, 2003).

Alzheimer's disease is a vicious affliction that can strike during middle age but usually emerges after age 65. The beginnings of Alzheimer's disease are so subtle they are often recognized only after the disease has progressed for a year or two. The hallmark early symptom is the forgetting of newly learned information after surprisingly brief periods of time (Albert & Killiany, 2001). The course of the disease is one of progressive deterioration, typically over a period of eight to ten years, ending in death (Neugroschl et al., 2005). In the beginning, victims simply lose the thread of conversations or forget to follow through on tasks they have started. Gradu-

ally, much more obvious problems begin to emerge, including difficulties in speaking, comprehending, and performing complicated tasks, as well as depression and sleep disturbance. Job performance deteriorates noticeably as victims forget important appointments and suffer indignities such as getting lost while driving and paying the same bill several times. From this point, profound memory loss develops. For example, patients may fail to recognize familiar people, something particularly devastating to family and friends. Many patients become restless and experience hallucinations, delusions, and paranoid thoughts. Eventually, victims become completely disoriented and are unable to care for themselves. There are some encouraging leads for treatments that might slow the progression of this horrific disease, but a cure does not appear to be on the horizon.

The causes that launch this debilitating neural meltdown are not well understood. Genetic factors clearly contribute, but their exact role remains unclear (Ashford & Mortimer, 2002). Some "protective" factors that reduce vulnerability to Alzheimer's disease have been identified, including regular exercise (Schuit et al., 2001) and frequent participation in stimulating cognitive activities (Wilson & Bennet, 2003). The importance of the latter factor emerged in a widely discussed longitudinal investigation called the Nun Study, which followed a group of elderly Catholic Nuns who agreed to donate their brains upon death. The findings of the Nun Study suggest that a high prevalence of positive emotions and strong engagement in mentally challenging work and recreation reduce one's risk for Alzheimer's disease (Danner, Snowdon, & Friesen, 2001; Snowdon, 2001).

Aging and Cognitive Changes

The evidence indicates that general intelligence is fairly stable throughout most of adulthood, with a small decline in *average* test scores often seen after age 60 (Schaie, 1990, 1994, 1996, 2005). However, this seemingly simple assertion masks many complexities and needs to be qualified carefully. First, group averages can be deceptive in that mean scores can be dragged down by a small minority of people who show a decline. For example, when Schaie (1990) calculated the percentage of people who maintain stable performance on various abilities (see **Figure 11.25**), he found that about 80% showed no decline by age 60 and that about two-thirds were still stable through age 81. Second, some forms of intelligence are more vulnerable to aging than oth-
Figure 11.25

Age and the stability of primary mental abilities. In his longitudinal study of cognitive performance begun in 1956, Schaie (1983, 1993) has repeatedly assessed the five basic mental abilities listed along the bottom of this chart. The data graphed here show the percentage of subjects who maintained stable levels of performance on each ability through various ages up to age 81. As you can see, even through the age of 81, the majority of subjects show no significant decline on most abilities.

SOURCE: Adapted from Schaie, K. W. (1990). Intellectual development in adulthood. In J. E. Birren and K. W. Schaie (Eds.), *Handbook of the psychology of aging* (pp. 291–309). San Diego: Academic Press. Copyright © 1990 Elsevier Science (USA), reproduced with permission from the publisher.

ers. Many theorists distinguish between *fluid intelligence,* **which involves basic reasoning ability, memory capacity, and speed of information processing,** versus *crystallized intelligence,* **which involves the ability to apply acquired knowledge and skills in problem solving.** Research suggests that fluid intelligence is much more likely to decline with age, whereas crystallized intelligence tends to remain stable (Baltes, Staudinger, & Lindenberger, 1999; Horn & Hofer, 1992; Li et al., 2004).

What about memory? Numerous studies report decreases in older adults' memory capabilities (Hoyer & Verhaeghen, 2006). Most researchers maintain that the memory losses associated with normal aging tend to be moderate and are *not* experienced by everyone (Dixon & Cohen, 2003; Shimamura et al., 1995). However, Salthouse (2003, 2004) takes a much more pessimistic view, arguing that age-related decreases in memory are substantial in magnitude, that they begin in early adulthood, and that they affect everyone. One reason for these varied conclusions may be that a variety of memory types can be assessed (see Chapter 7 for a review of various systems of memory). The most reliable decrements are usually seen in *episodic memory* and *working memory,* with less consistent losses observed on tasks involv-

ing *procedural memory* and *semantic memory* (Dixon & Cohen, 2003; Hoyer & Verhaeghen, 2006).

In the cognitive domain, aging seems to take its toll on *speed* first. Many studies indicate that speed in learning, solving problems, and processing information tends to decline with age (Salthouse, 1996). The evidence suggests that the erosion of processing speed may be a gradual, lengthy trend beginning in middle adulthood (see **Figure 11.26**). The general nature of this trend (across differing tasks) suggests that it may be the result of age-related changes in neurological functioning (Salthouse, 2000). Some theorists believe that diminished mental speed is the key factor underlying the age-related declines seen on many, varied cognitive tasks (Salthouse, 2005), although doubts have been raised about this conclusion (Hartley, 2006). Even though mental speed declines with age, problem-solving ability remains largely unimpaired if older people are given adequate time to compensate for their reduced speed.

It should be emphasized that many people remain capable of great intellectual accomplishments well into their later years (Simonton, 1990, 1997). This fact was verified in a study of scholarly, scientific, and artistic productivity that examined lifelong patterns of work among 738 men who lived at least through the age of 79. Dennis (1966) found that the 40s decade was the most productive in most professions. However, productivity was remarkably stable through the 60s and even the 70s in many areas.

A hot issue in recent years has been whether high levels of mental activity in late adulthood can delay the typical age-related declines in cognitive functioning. This possibility is sometimes referred to as the "use it or lose it" hypothesis. Several lines of evidence seem to provide support for this notion. For example, people who continue to work further into old age, especially people who remain in mentally demanding jobs, tend to show smaller decrements in cognitive abilities than their age-mates (Bosma et al., 2002; Schooler, 2007). Other studies suggest that continuing to engage in intellectually challenging activities in late adulthood serves to buffer against cognitive declines (Hultsch et al., 1999; Kliegel, Zimprich, & Rott, 2004). The evidence is complex and there are skeptics (Salthouse, 2006), but it appears that keeping mentally active may help elderly people delay and diminish the negative effects of aging on cognitive functioning.

Figure 11.26

Age and mental speed. Many studies have found that mental speed decreases with age. The data shown here, from Salthouse (2000), are based on two perceptual speed tasks. The data points are means for large groups of subjects expressed in terms of how many standard deviations (see Chapter 2) they are above or below the mean for all ages (which is set at 0). Similar age-related declines are seen on many tasks that depend on mental speed.

Reflecting on the Chapter's Themes

Many of our seven integrative themes surfaced to some degree in our coverage of human development. We saw theoretical diversity in the discussions of attachment, cognitive development, and personality development. We saw that psychology evolves in a sociohistorical context, investigating complex, real-world issues. We encountered multifactorial causation of behavior in the development of temperament and attachment, among other things. We saw cultural invariance and cultural diversity in our examination of attachment, motor development, cognitive development, and moral development.

But above all else, we saw how heredity and environment jointly mold behavior. We've encountered the dual influence of heredity and environment before, but this theme is rich in complexity, and each chapter draws out different aspects and implications. Our discussion of development amplified the point that genetics and experience work *interactively* to shape behavior. In the language of science, an interaction means that the effects of one variable depend on the effects of another. In other words, heredity and environment do not operate independently. Children with "difficult" temperaments will elicit different reactions from different parents, depending on the parents' personalities and expecta-

tions. Likewise, a particular pair of parents will affect children in different ways, depending on the inborn characteristics of the children. An interplay, or feedback loop, exists between biological and environmental factors. For instance, a temperamentally difficult child may elicit negative reactions from parents, which serve to make the child more difficult, which evokes more negative reactions. If this child develops into an ornery 11-year-old, which do we blame—genetics or experience? Clearly, this outcome is due to the reciprocal effects of both.

All aspects of development are shaped jointly by heredity and experience. We often estimate their relative weight or influence, as if we could cleanly divide behavior into genetic and environmental components. Although we can't really carve up behavior that neatly, such comparisons can be of great theoretical interest, as you'll see in our upcoming Personal Application, which discusses the nature and origins of gender differences in behavior.

REVIEW of Key Learning Goals
11.21 This chapter showed that psychology is theoretically diverse, that psychology evolves in a sociohistorical context, that multifactorial causation is the norm, and that culture affects many aspects of behavior, but above all else, it demonstrated that heredity and environment jointly mold behavior.

Understanding Gender Differences

Answer the following "true" or "false."
____ **1** Females are more socially oriented than males.
____ **2** Males outperform females on most spatial tasks.
____ **3** Females are more irrational than males.
____ **4** Males are less sensitive to nonverbal cues than females.
____ **5** Females are more emotional than males.

Are there genuine behavioral differences between the sexes similar to those mentioned

above? If so, why do these differences exist? How do they develop? These are the complex and controversial questions that we'll explore in this Personal Application.

Before proceeding further, we need to clarify how some key terms are used, as terminology in this area of research has been evolving and remains a source of confusion. *Sex usually refers to the biologically based categories of female and male.* In contrast, *gender usually refers to culturally constructed distinctions between femininity and masculinity.* Individuals are born female or male. However, they

Key Learning Goals
11.22 Summarize evidence on gender differences in behavior, and assess the significance of these differences.
11.23 Explain how biological factors are thought to contribute to gender differences.
11.24 Explain how environmental factors are thought to contribute to gender differences.

become feminine or masculine through complex developmental processes that take years to unfold.

The statements at the beginning of this Application reflect popular gender stereotypes in our society. *Gender stereotypes* are

STAGE OF DEVELOPMENT

INFANCY (BIRTH–2)

PHYSICAL AND SENSORIMOTOR DEVELOPMENT
Rapid brain growth; 75% of adult brain weight is attained by age 2.

Rapid improvement occurs in visual acuity; depth perception is clearly present by 6 months, perhaps earlier.

Ability to localize sounds is apparent at birth; ability to recognize parent's voice occurs within first week.

Landmarks in motor development: Infants sit without support around 6 months, walk around 12–14 months, run freely around 2 years.

MAJOR STAGE THEORIES

PIAGET	Sensorimotor	
KOHLBERG	Premoral	
ERIKSON	Trust vs. mistrust	Autonomy vs. shame
FREUD (see Chapter 12)	Oral	Anal

COGNITIVE DEVELOPMENT

Object permanence gradually develops.

Infant shows orienting response (pupils dilate, head turns) and attention to new stimulus, habituation (reduced orienting response) to repeated stimulus.

Babbling increasingly resembles spoken language.

First word is used around age 1; vocabulary spurt begins around 18 months; frequent overextensions (words applied too broadly) occur.

SOCIAL AND PERSONALITY DEVELOPMENT
Temperamental individuality is established by 2–3 months; infants tend to be easy, difficult, or slow to warm up.

© George Silver/Corbis

Attachment to caregiver(s) is usually evident around 6–8 months; secure attachment facilitates exploration.

"Stranger anxiety" often appears around 6–8 months; separation anxiety peaks around 14–18 months.

Information compiled by Barbara Hansen Lemme, College of DuPage

EARLY CHILDHOOD (2–6)

Connections among neurons continue to increase in density.

Visual acuity reaches 20/20.

Bladder and bowel control is established.

Hand preference is usually solidified by 3–4 years; coordination improves; children learn to dress themselves.
MIDDLE CHILDHOOD (6–12)

In girls, growth spurt begins around age 11, bringing dramatic increases in height and weight.

Levels of pituitary activity and sex hormones increase.

Girls' secondary sex characteristics (such as breast development and widening hips) begin to emerge.

In girls, puberty begins around age 12; menstruation starts.

Preoperational	Concrete operational
Preconventional	Conventional
Initiative vs. guilt	Industry vs. inferiority
Phallic	Latency

Thought is marked by egocentrism (limited ability to view world from another's perspective).

Thought is marked by centration (inability to focus on more than one aspect of a problem at a time) and irreversibility (inability to mentally undo an action).

Telegraphic speech (omitting nonessential words) appears at 2–3 years; syntax is well developed by age 5; vocabulary increases dramatically.

Short-term memory capacity increases from two items at age 2 to five items around age 6–7; attention span improves.

Conservation (understanding that physical qualities can remain constant in spite of transformations in shape) is gradually mastered.

Child develops decentration (ability to focus on more than one feature of a problem at a time) and reversibility (ability to mentally undo an action).

Metalinguistic awareness (ability to reflect on use of language) leads to play with language, use of puns, riddles, metaphors.

Long-term memory improves with increasing use of encoding strategies of rehearsal and organization.

© David Young-Wolff/PhotoEdit

Child realizes that gender does not change and begins to learn gender roles and form gender identity; social behavior is influenced by observational learning, resulting in imitation.

Child progresses from parallel (side-by-side, noninteractive) play to cooperative play.

Social world is extended beyond family; first friendships are formed.

© Jon Feingersh/Corbis

Child experiences great increase in social skills, improved understanding of others' feelings; social world is dominated by same-sex peer relationships.

Role-taking skills emerge; fantasy is basis for thoughts about vocations and jobs.

Altruism tends to increase, agression tends to decrease; aggression tends to become more verbal rather than physical, hostile more than instrumental.

Continued on next page

ADOLESCENCE (12–20)

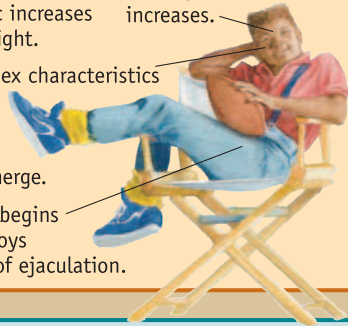
YOUNG ADULTHOOD (20–40)

Physical and sensorimotor development
continued

In boys, growth spurt begins around age 13, bringing dramatic increases in height and weight.

Level of pituitary activity and hormones increases.

Boys' secondary sex characteristics (such as voice change and growth of facial hair) begin to emerge.

In boys, puberty begins around age 14; boys become capable of ejaculation.


Reaction time and muscular strength peak in early to mid-20s.

Maximum functioning of all body systems, including senses, attained; slow decline begins in 20s.
External signs of aging begin to show in 30s; skin loses elasticity; hair is thinner, more likely to be gray.

Lowered metabolic rate contributes to increased body fat relative to muscle; gain in weight is common.

Major stage theories
continued

Formal operational

Postconventional (if attained)

Identity vs. confusion

Intimacy vs. isolation

Genital

Cognitive development
continued

Deductive reasoning improves; problem solving becomes more systematic, with alternative possibilities considered before solution is selected.

Thought becomes more abstract and reflective; individual develops ability to mentally manipulate abstract concepts as well as concrete objects.

Individual engages in idealistic contemplation of hypotheticals, "what could be."

Long-term memory continues to improve as elaboration is added to encoding strategies.

Intellectual abilities and speed of information processing are stable.

Greater emphasis is on application, rather than acquisition, of knowledge.

There is some evidence of a trend toward dialectical thought (ideas stimulate opposing ideas), leading to more contemplation of contradictions, pros and cons.

Social and personality development
continued

Person experiences increased interactions with opposite-sex peers; dating begins.

Attention is devoted to identify formation, questions such as "Who am I?" and "What do I want out of life?"

Realistic considerations about abilities and training requirements become more influential in thoughts about vocations and jobs.

Energies are focused on intimate relationships, learning to live with marriage partner, starting a family, managing a home.

Trial period is given for occupational choices, followed by stabilization of vocational commitment; emphasis is on self-reliance, becoming one's own person.

For many, close relationship develops with mentor (older person who serves as role model, adviser, and teacher).

© David Young-Wolff/PhotoEdit

© Radius Images/Alamy

MIDDLE ADULTHOOD (40–65)

Changes occur in vision: increased farsightedness and difficulty recovering from glare; slower dark adaptation.

The amount of brain tissue declines, but significance of this neural loss is unclear.

In women, menopause occurs around age 50; in both sexes, sexual activity declines, although capacity for arousal changes only slightly.

Sensitivity to high-frequency sounds decreases, especially in males after age 55.

LATE ADULTHOOD (65 AND OLDER)

Height decreases slightly because of changes in vertebral column; decline in weight also common.

Sensitivity of vision, hearing, and taste noticeably decreases.

Chronic diseases, especially heart disease, cancer, and stroke, increase.

Rate of aging is highly individualized.

Generativity vs. self-absorption

Integrity vs. despair

There is some evidence for a trend toward improved judgment or "wisdom" based on accumulation of life experiences.

Effectiveness of retrieval from long-term memory begins slow decline, usually not noticeable until after age 55.

Individual experiences gradual decline in speed of learning, problem solving, and information processing.

In spite of decreased speed in cognitive processes, intellectual productivity and problem-solving skills usually remain stable.

Midlife transition around age 40 leads to reflection, increased awareness of mortality and passage of time, but usually is not a personal crisis.

"Sandwich generation" is caught between needs of aging parents and children reaching adulthood.

Career development peaks; there is some tendency to shift energy from career concerns to family concerns.

Individual experiences gradual decline in cognitive speed and effectiveness of working memory.

Intellectual productivity depends on factors such as health and lifestyle; many people in their 60s and 70s remain quite productive.

Decision making tends to become more cautious.

Fluid intelligence often declines, but crystallized intelligence remains stable or increases.

Physical changes associated with aging require adjustments that affect life satisfaction.

Marital satisfaction often increases, but eventually death of spouse presents coping challenge.

Living arrangements are a significant determinant of satisfaction, as 60%–90% of time is spent at home.

widely held beliefs about females' and males' abilities, personality traits, and social behavior. Table 11.1 lists some characteristics that are part of the masculine and feminine stereotypes in North American society. The table shows something you may have already noticed on your own: The male stereotype is much more flattering, suggesting that men have virtually cornered the market on competence and rationality. After all, everyone knows that females are more dependent, emotional, irrational, submissive, and talkative than males. Right? Or is that not the case? Let's look at the research.

How Do the Sexes Differ in Behavior?

Gender differences are actual disparities between the sexes in typical behavior or

Table 11.1 Elements of Traditional Gender Stereotypes

Masculine	Feminine
Active	Aware of other's feelings
Adventurous	Considerate
Aggressive	Creative
Ambitious	Cries easily
Competitive	Devotes self to others
Dominant	Emotional
Independent	Enjoys art and music
Leadership qualities	Excitable in a crisis
Likes math and science	Expresses tender feelings
Makes decisions easily	Feelings hurt
Mechanical aptitude	Gentle
Not easily influenced	Home oriented
Outspoken	Kind
Persistent	Likes children
Self-confident	Neat
Skilled in business	Needs approval
Stands up under pressure	Tactful
Takes a stand	Understanding

Source: Adapted from Ruble, T. L. (1983). Sex stereotypes: Issues of change in the 70s. *Sex Roles, 9,* 397–402. Copyright © 1983 Plenum Publishing Group. Adapted with kind permission of Springer Science and Business Media.

average ability. Mountains of research, literally thousands of studies, exist on gender differences. What does this research show? Are the stereotypes of males and females accurate? Well, the findings are a mixed bag. The research indicates that genuine behavioral differences *do* exist between the sexes and that people's stereotypes are not entirely inaccurate (Eagly, 1995; Halpern, 2000). But the differences are fewer in number, smaller in size, and far more complex than stereotypes suggest. As you'll see, only two of the differences mentioned in our opening true-false questions (the even-numbered items) have been largely supported by research.

Cognitive Abilities

In the cognitive domain, it appears that there are three genuine—albeit rather small—gender differences. First, on the average, females tend to exhibit slightly better *verbal skills* than males (Halpern et al., 2007). In particular, females seem stronger on tasks that require rapid access to semantic information in long-term memory and tasks that require the production or comprehension of complex prose (Halpern, 2004). Second, starting during high school, males show a slight advantage on tests of *mathematical ability.* When all students are compared, males' advantage is quite small (Hyde, 2005a). However, at the high end of the ability distribution, the gender gap is larger, as quite a few more males than females are found to have exceptional math skills (Halpern et al., 2007). Third, starting in the grade-school years, males tend to score higher than females on most measures of *visual-spatial ability* (Halpern et al., 2007). The size of these gender differences varies depending on the exact nature of the spatial task. Males appear to be strongest on tasks that require mental rotations or tracking the movement of objects through three-dimensional space (Halpern, 2004).

Social Behavior

In regard to social behavior, research findings support the existence of some additional gender differences. First, studies indicate that males tend to be much more *physically aggressive* than females (Archer, 2005). This disparity shows up early in childhood. Its continuation into adulthood

is supported by the fact that men account for a grossly disproportionate number of the violent crimes in our society (Kenrick, Trost, & Sundie, 2004). The findings on *verbal aggression* are more complex, as females appear to exhibit more relational aggression (snide remarks and so forth) (Archer, 2005). Second, there are gender differences in *nonverbal communication and interpersonal sensitivity.* The evidence indicates that females are more sensitive than males to subtle nonverbal cues (Hall, Carter, & Horgan, 2000; Hampson, van Anders, & Mullin, 2006) and that they pay more attention to interpersonal information (Hall & Mast, 2008). Third, males are more sexually active than females in a variety of ways, and they have more permissive attitudes about casual, premarital, and extramarital sex (Baumeister et al., 2001b; Hyde, 2005; see Chapter 10).

Some Qualifications

Although research has identified some genuine gender differences in behavior, bear in mind that these are group differences that indicate nothing about individuals. Essentially, research results compare the "average man" with the "average woman." However, you are—and every individual is—unique. The average female and male are ultimately figments of our imagination. Furthermore, the genuine group differences noted are relatively small (Hyde, 2005a). **Figure 11.27** shows how scores on a trait, perhaps verbal ability, might be distributed for men and women. Although the group averages are detectably different, you can see the great variability within each group (sex) and the huge overlap between the two group distributions.

Biological Origins of Gender Differences

What accounts for the development of various gender differences? To what degree are they the product of learning or of biology? This question is yet another manifestation of the nature versus nurture issue. Investigations of the biological origins of gender differences have centered on the evolutionary bases of behavior, hormones, and brain organization.
Figure 11.27
The nature of gender differences. Gender differences are group differences that indicate little about individuals because of the great overlap between the groups. For a given trait, one sex may score higher on the average, but far more variation occurs within each sex than between the sexes.

Evolutionary Explanations

Evolutionary analyses usually begin by arguing that gender differences in behavior are largely the same across divergent cultures because cultural invariance suggests that biological factors are at work. Although research has turned up some fascinating exceptions, the better-documented gender differences in cognitive abilities, aggression, and sexual behavior *are* found in virtually all cultures (Beller & Gafni, 1996; Kenrick et al., 2004). Evolutionary psychologists go on to argue that these universal gender differences reflect different natural selection pressures operating on males and females over the course of human history (Archer, 1996; Buss & Kenrick, 1998). For example, as we discussed in Chapter 10, males supposedly are more sexually active and permissive because they invest less than females in the process of procreation and can maximize their reproductive success by seeking many sexual partners (Buss, 1996; Schmitt, 2005). The gender gap in aggression is also explained in terms of reproductive fitness. Because females are more selective about mating than males, males have to engage in more competition for sexual partners than females do. Greater aggressiveness is thought to be adaptive for males in this competition for sexual access, as it should foster social dominance over other males and facilitate the acquisition of the material resources emphasized by females when they evaluate potential partners (Campbell, 2005; Cummins, 2005). Evolutionary theorists assert that gender differences in spatial ability reflect the division of labor in ancestral hunting-and-gathering societies in which males typically handled the hunting and females the gathering. Males' superior-

ity on most spatial tasks has been attributed to the adaptive demands of hunting (Silverman & Choi, 2005; see Chapter 1).

Evolutionary analyses of gender differences are interesting, but controversial. On the one hand, it seems eminently plausible that evolutionary forces could have led to some divergence between males and females in typical behavior. On the other hand, evolutionary hypotheses are highly speculative and difficult to test empirically (Eagly & Wood, 1999; Halpern, 2000). The crucial problem for some critics is that evolutionary analyses are so "flexible," they can be used to explain almost anything. For example, if the situation regarding spatial ability were reversed—if females scored higher than males—evolutionary theorists might attribute females' superiority to the adaptive demands of gathering food, weaving baskets, and making clothes—and it would be difficult to prove otherwise (Cornell, 1997).

The Role of Hormones

Disparities between males and females in hormone levels may contribute to gender differences in behavior (Hampson & Moffat, 2004). Hormones play a key role in sexual differentiation during prenatal development. The high level of androgens (the principal class of male hormones) in males and the low level of androgens in females lead to the differentiation of male and female genital organs. The critical role of prenatal hormones becomes apparent when something interferes with normal prenatal hormonal secretions. About a half-dozen endocrine disorders can cause overproduction or underproduction of specific gonadal hormones during prenatal development.

Scientists have also studied children born to mothers who were given an androgen-like drug to prevent miscarriage. The general trend in this research is that females exposed prenatally to abnormally high levels of androgens exhibit more male-typical behavior than other females do and that males exposed prenatally to abnormally low levels of androgens exhibit more female-typical behavior than other males (Hines, 2004).

These findings suggest that prenatal hormones contribute to the shaping of gender differences in humans. But there are some problems with this evidence (Basow, 1992; Fausto-Sterling, 1992). First, the evidence is much stronger for females than for males. Second, it's always dangerous to draw conclusions about the general population based on small samples of people who have abnormal conditions. Looking at the evidence as a whole, it does seem likely that hormones contribute to gender differences in behavior. However, a great deal remains to be learned.

Differences in Brain Organization

Many theorists believe that gender differences in behavior are rooted in male-female disparities in brain structure and organization (Cahill, 2006). For example, some theorists have tried to link gender differences to the specialization of the cerebral hemispheres in the brain (see **Figure 11.28** on the next page). As you may recall from Chapter 3, in most people the left hemisphere is more actively involved in verbal processing, whereas the right hemisphere is more active in visual-spatial processing (Springer & Deutsch, 1998). After these findings surfaced, theorists began to wonder whether this division of labor in the brain might be related to gender differences in verbal and spatial skills. Consequently, they began looking for sex-related disparities in brain organization.

Some thought-provoking findings *have* been reported. For instance, some studies have found that *males tend to exhibit more cerebral specialization than females* (Hellige, 1993b; Voyer, 1996). In other words, males tend to depend more heavily than females do on the left hemisphere in verbal processing and more heavily on the right hemisphere in spatial processing. Differences
Corpus callosum

Figure 11.28

The cerebral hemispheres and the corpus callosum. In this drawing the cerebral hemispheres have been "pulled apart" to reveal the corpus callosum, the band of fibers that connects the right and left halves of the brain. Research has shown that the right and left hemispheres are specialized to handle different types of cognitive tasks (see Chapter 3), leading some theorists to speculate that patterns of hemispheric specialization might contribute to gender differences in verbal and spatial abilities.

between males and females have also been found in the size of the corpus callosum, the band of fibers that connects the two hemispheres of the brain. Some studies suggest that *females tend to have a larger corpus callosum* (Bigler et al., 1997), which might allow for better interhemispheric transfer of information, which, in turn, might underlie the less lateralized organization of females' brains (Innocenti, 1994). Thus, some theorists have concluded that differences between the sexes in brain organization are responsible for gender differences in verbal and spatial ability (Geschwind & Galaburda, 1987; Kimura & Hampson, 1993).

This idea is intriguing, but psychologists have a long way to go before they can explain gender differences in terms of right brain/left brain specialization. Studies have not been consistent in finding that males have more specialized brain organization than females (Halpern, 1992; Kinsbourne,

1980), and the finding of a larger corpus callosum in females has proven controversial (Halpern et al., 2007). Moreover, even if these findings were replicated consistently, no one is really sure just how they would account for the observed gender differences in cognitive abilities.

In summary, researchers have made some intriguing progress in their efforts to document the biological roots of gender differences in behavior. However, the idea that "anatomy is destiny" has proven difficult to demonstrate. Many theorists remain convinced that gender differences are largely shaped by experience. Let's examine their evidence.

Environmental Origins of Gender Differences

Socialization **is the acquisition of the norms and behaviors expected of people in a particular society.** In all cultures, the socialization process includes efforts to train children about gender roles. *Gender roles* **are expectations about what is appropriate behavior for each sex.** Although gender roles are in a period of transition in modern Western society, there are still many disparities in how males and females are brought up. Investigators have identified three key processes involved in the development of gender roles: operant conditioning, observational learning, and self-socialization. First we'll examine these processes. Then we'll look at the principal sources of gender-role socialization: families, schools, and the media.

Operant Conditioning

In part, gender roles are shaped by the power of reward and punishment—the key processes in *operant conditioning* (see Chapter 6). Parents, teachers, peers, and others often reinforce (usually with tacit approval) "gender-appropriate" behavior and respond negatively to "gender-inappropriate" behavior (Bussey & Bandura, 1999; Matlin, 2008). If you're a man, you might recall getting hurt as a young boy and being told that "big boys don't cry." If you succeeded in inhibiting your crying, you may have earned an approving smile or even something tan-

gible like an ice cream cone. The reinforcement probably strengthened your tendency to "act like a man" and suppress emotional displays. If you're a woman, chances are your crying wasn't discouraged as gender-inappropriate. Studies suggest that fathers encourage and reward gender-appropriate behavior in their youngsters more than mothers do and that boys experience more pressure to behave in gender-appropriate ways than girls do (Levy, Taylor, & Gelman, 1995).

Observational Learning

Observational learning (see Chapter 6) by children can lead to the imitation of adults' gender-appropriate behavior. Children imitate both males and females, but most children tend to imitate same-sex role models more than opposite-sex role models (Bussey & Bandura, 2004). Thus, imitation often leads young girls to play with dolls, dollhouses, and toy stoves. Young boys are more likely to tinker with toy trucks, miniature gas stations, or tool kits.

Self-Socialization

Children themselves are active agents in their own gender-role socialization. Several *cognitive theories* of gender-role development emphasize self-socialization (Bem, 1985; Cross & Markus, 1993; Martin & Ruble, 2004). Self-socialization entails three steps. First, children learn to classify themselves as male or female and to recognize their sex as a permanent quality (around ages 5 to 7). Second, this self-categorization motivates them to value those characteristics and behaviors associated with their sex. Third, they strive to bring their behavior in line with what is considered gender-appropriate in their culture. In other words, children get involved in their own socialization, working diligently to discover the rules that are supposed to govern their behavior.

Sources of Gender-Role Socialization

There are three main sources of influence in gender-role socialization: families, schools, and the media. Of course, we are now in an era of transition in gender roles, so the generalizations that follow may say more about

The socialization of gender roles begins very early, as parents dress their infants in gendered clothing, buy them gender-driven toys, and encourage them to participate in "gender-appropriate" activities.

how you were socialized than about how children will be socialized in the future.

Families. A great deal of gender-role socialization takes place in the home (McHale, Crouter, & Whiteman, 2003; Pomerantz, Ng, & Wang, 2004). Fathers engage in more "rough-housing" play with their sons than with their daughters, even in infancy (McBride-Chang & Jacklin, 1993). As children grow, boys and girls are encouraged to play with different types of toys (Wood, Desmarais, & Gugula, 2002). Generally, boys have less leeway to play with "feminine" toys than girls do with "masculine" toys. When children are old enough to help with household chores, the assignments tend to depend on sex (Cunningham, 2001). For example, girls wash dishes and boys mow the lawn. And parents are more likely to explain scientific concepts to boys than to girls (Crowley et al., 2001).

Schools. Schools and teachers clearly contribute to the socialization of gender roles. The books that children use in learning to read can influence their ideas about what is suitable behavior for males and females (Diekman & Murnen, 2004). Traditionally, males have been more likely to be portrayed as clever, heroic, and adventurous in these books, while females have been more likely to be shown doing domestic chores. Preschool and grade-school teachers frequently reward sex-appropriate behavior in their pupils (Fagot et al., 1985; Ruble & Martin, 1998). Interestingly, teachers tend to pay greater attention to males, helping them, praising them, and scolding them more than females (Sadker & Sadker, 1994).

Media. Television and other mass media are another source of gender-role socialization (Bussey & Bandura, 2004). Although some improvement has been made in recent years, television shows have traditionally depicted men and women in stereotypical ways (Galambos, 2004; Signorielli, 2001). Women are often portrayed as submissive, passive, and emotional. Men are more likely to be portrayed as independent, assertive, and competent. Even commercials contribute to the socialization of gender roles (Furnham & Mak, 1999; Signorielli, McLeod, & Healy, 1994). Women are routinely shown worrying about trivial matters such as the whiteness of their laundry or the shine of their dishes.

Conclusion

As you can see, the findings on gender and behavior are complex and confusing. Nonetheless, the evidence does permit one very general conclusion—a conclusion that you have seen before and will see again. Taken as a whole, the research in this area suggests that biological factors and environmental factors both contribute to gender differences in behavior—as they do to all other aspects of development.

Who is this teacher going to call on? Although girls tend to perform better in grade school, research suggests that grade-school teachers pay more attention to boys.

REVIEW of Key Learning Goals

11.22 Gender differences in behavior are fewer in number than gender stereotypes suggest. In the cognitive domain, research reviews suggest that there are genuine gender differences in verbal ability, mathematical ability, and spatial ability. In regard to social behavior, differences have been found in aggression, nonverbal communication, and sexual behavior. But most gender differences in behavior are very small in magnitude.

11.23 Evolutionary theorists maintain that gender differences transcend culture because males and females have confronted different adaptive demands over the course of human history. Extensive evidence suggests that prenatal hormones contribute to human gender differences, but the research is marred by interpretive problems. Research linking gender differences to cerebral specialization is intriguing, but much remains to be learned.

11.24 A vast research literature shows that gender differences are shaped by socialization processes. Operant conditioning, observational learning, and self-socialization contribute to the development of gender differences. Families, schools, and the media are among the main sources of gender-role socialization.

Key Learning Goals

11.25 Clarify and critique the argument that fathers are essential for healthy development.

Are Fathers Essential to Children's Well-Being?

Are fathers crucial to children's well-being? This seemingly simple question has sparked heated debate.

© Royalty Free/Corbis

Are fathers essential for children to experience normal, healthy development? This question is currently the subject of heated debate. In recent years, a number of social scientists have mounted a thought-provoking argument that father absence due to divorce, abandonment, and so forth, is the chief factor underlying a host of modern social ills. For example, David Blankenhorn (1995) argues that "fatherlessness is the most harmful demographic trend of this generation. It is the leading cause of declining child well-being in our society" (p. 1). Expressing a similar view, David Popenoe (1996) maintains that "today's fatherlessness has led to social turmoil-damaged children, unhappy children, aimless children, children who strike back with pathological behavior and violence" (p.192).

The Basic Argument

What is the evidence for the proposition that fathers are essential to healthy development? Over the last 40 years, the proportion of children growing up without a father in the home has more than doubled. During the same time, we have seen dramatic increases in teenage pregnancy, juvenile delinquency, violent crime, drug abuse, eating disorders, teen suicide, and family dysfunction. Moreover, mountains of studies have demonstrated an association between father absence and an elevated risk for these problems. Summarizing this evidence, Popenoe (1996) asserts that "fatherless children have a risk factor two to three times that of fathered children for a wide range of negative outcomes, including dropping out of high school, giving birth as a teenager, and becoming a juvenile delinquent" (p. 192), which leads him to infer that "fathers have a unique and irreplaceable role to play in child development" (p. 197). Working from this premise, Popenoe concludes, "If present trends continue, our so-

ciety could be on the verge of committing social suicide" (p. 192). Echoing this dire conclusion, Blankenhorn (1995) comments that "to tolerate the trend of fatherlessness is to accept the inevitability of continued societal recession" (p. 222).

You might be thinking, "What's all the fuss about?" Surely, proclaiming the importance of fatherhood ought to be no more controversial than advocacy for motherhood or apple pie. But the assertion that a father is essential to a child's well-being has some interesting sociopolitical implications. It suggests that heterosexual marriage is the only appropriate context in which to raise children and that other family configurations are fundamentally deficient. Based on this line of reasoning, some people have argued for new laws that would make it more difficult to obtain a divorce and other policies and programs that would favor traditional families over families headed by single mothers, cohabiting parents, and gay and lesbian parents (Silverstein & Auerbach, 1999). Thus, the

question about the importance of fathers is creating a great deal of controversy, because it is really a question about alternatives to traditional family structure.

Evaluating the Argument

In light of the far-reaching implications of the view that fathers are essential to normal development, it makes sense to subject this view to critical scrutiny. How could you use critical thinking skills to evaluate this argument? At least three previously discussed ideas seem pertinent.

First, it is important to recognize that the position that fathers are essential for healthy development rests on a foundation of correlational evidence, and as we have seen repeatedly, *correlation is no assurance of causation*. Yes, there has been an increase in fatherlessness that has been paralleled by increases in teenage pregnancy, drug abuse, eating disorders, and other disturbing social problems. But think of all the other changes that have occurred in American culture

over the last 40 years, such as the decline of organized religion, the growth of mass media, dramatic shifts in sexual mores, and so forth. Increased fatherlessness has co-varied with a host of other cultural trends. Hence, it is highly speculative to infer that father absence is the chief cause of most modern social maladies.

Second, it always pays to think about whether there are specific, *alternative explanations* for findings that you might have doubts about. What other factors might account for the association between father absence and children's maladjustment? Think for a moment: What is the most frequent cause of father absence? Obviously, it is divorce. Divorces tend to be highly stressful events that disrupt children's entire lives. Although the evidence suggests that a majority of children seem to survive divorce without lasting, detrimental effects, it is clear that divorce elevates youngsters' risk for a wide range of negative developmental outcomes (Amato, 2001, 2003; Hetherington, 1999, 2003). Given that father absence and divorce are inextricably intertwined, it is possible that the negative effects of divorce account for much of the association between father absence and social problems.

Are there any other alternative explanations for the correlation between fatherlessness and social maladies? Yes, critics point out that the prevalence of father absence co-varies with socioeconomic status. Father absence is much more common in low-income families (Anderson, Kohler, & Letiecq, 2002). Thus, the effects of father absence are entangled to some extent with the many powerful, malignant effects of poverty, which might account for much of the correlation between fatherlessness and negative outcomes (McLoyd, 1998).

A third possible strategy in thinking critically about the effects of father absence would be to look for some of the *fallacies in reasoning* introduced in Chapter 10 (irrelevant reasons, circular reasoning, slippery slope, weak analogies, and false dichotomy). A couple of the quotes from Popenoe and Blankenhorn were chosen to give you an opportunity to detect two of these fallacies in a new context. Take a look at the quotes once again and see whether you can spot the fallacies.

Popenoe's assertion that "if present trends continue, our society could be on the verge of social suicide" is an example of *slippery slope argumentation,* which involves predictions that if one allows X to happen, things will spin out of control and catastrophic events will follow. "Social suicide" is a little vague, but it sounds as if Popenoe is predicting that father absence will lead to the destruction of modern American culture. The other fallacy that you might have spotted was the *false dichotomy* apparent in Blankenhorn's assertion that "to tolerate the trend of fatherlessness is to accept the inevitability of continued societal recession." A false dichotomy creates an either-or choice between the position one wants to advocate (in this case, new social policies to reduce father absence) and some obviously horrible outcome that any sensible person would want to avoid (social decay), while ignoring other possible outcomes that might lie between these extremes.

In summary, we can find a number of flaws and weaknesses in the argument that fathers are *essential* to normal development. However, our critical evaluation of this argument *does not mean that fathers are unimportant.* Many types of evidence suggest that fathers generally make significant contributions to their children's development (Carlson, 2006; Lewis & Lamb, 2003; Rohner & Veneziano, 2001). We could argue with merit that fathers typically provide a substantial advantage for children that fatherless children do not have. But there is a crucial distinction between arguing that fathers *promote* normal, healthy development and arguing that fathers are *necessary* for normal, healthy development. If fathers are *necessary,* children who grow up without them could not achieve the same level of well-being as those who have fathers, yet it is clear that a great many children from single-parent homes turn out just fine.

Fathers surely are important, and it seems likely that father absence *contributes* to a variety of social maladies. So, why do Blankenhorn (1995) and Popenoe (1996) argue for the much stronger conclusion—that fathers are *essential?* They appear to prefer the stronger conclusion because it raises much more serious questions about the viability of nontraditional family forms. Thus, they seem to want to advance a *political agenda* that champions traditional family values. They are certainly entitled to do so, but when research findings are used to advance a political agenda—whether conservative or liberal—a special caution alert should go off in your head. When a political agenda is at stake, it pays to scrutinize arguments with extra care, because research findings are more likely to be presented in a slanted fashion. The field of psychology deals with a host of complex questions that have profound implications for a wide range of social issues. The skills and habits of critical thinking can help you find your way through the maze of reasons and evidence that hold up the many sides of these complicated issues.

Table 11.2 Critical Thinking Skills Discussed in This Application

Skill	Description
Understanding the limitations of correlational evidence	The critical thinker understands that a correlation between two variables does not demonstrate that there is a causal link between the variables.
Looking for alternative explanations for findings and events	In evaluating explanations, the critical thinker explores whether there are other explanations that could also account for the findings or events under scrutiny.
Recognizing and avoiding common fallacies, such as irrelevant reasons, circular reasoning, slippery slope reasoning, weak analogies, and false dichotomies	The critical thinker is vigilant about conclusions based on unrelated premises, conclusions that are rewordings of premises, unwarranted predictions that things will spin out of control, superficial analogies, and contrived dichotomies.

REVIEW of Key Learning Goals

11.25 Some social scientists have argued that father absence is the chief cause of a host of social problems and that fathers are essential for normal, healthy development. Critics note that all the relevant data are correlational, making causal inferences speculative, and they argue that there are alternative explanations for the association between father absence and negative developmental outcomes.

Key Ideas

Progress Before Birth: Prenatal Development

❚ Prenatal development proceeds through the germinal, embryonic, and fetal stages as the zygote is differentiated into a human organism. During this period, development may be affected by maternal malnutrition, maternal drug use, and some maternal illnesses.

The Wondrous Years of Childhood

❚ Motor development follows cephalocaudal and proximodistal trends. Early motor development depends on both maturation and learning. Developmental norms for motor skills and other types of development only reflect typical performance.

❚ Temperamental differences among children are apparent during the first few months of life. These differences are fairly stable and may influence adult personality. Harlow's work with monkeys undermined the reinforcement explanation of attachment. Bowlby proposed an evolutionary explanation that has been influential.

❚ Research shows that attachment emerges out of an interplay between infant and mother. Infant-mother attachments fall into four categories: secure, anxious-ambivalent, avoidant, and disorganized-disoriented. Attachment patterns may have lasting effects on individuals. Modest cultural variations in the prevalence of various patterns of attachment are seen, but secure attachment predominates in all cultures.

❚ Erikson's theory of personality development proposes that individuals evolve through eight stages over the life span. In each stage the person wrestles with changes (crises) in social relationships.

❚ According to Piaget's theory of cognitive development, the key advance during the sensorimotor period is the child's gradual recognition of the permanence of objects. The preoperational period is marked by certain deficiencies in thinking—notably, centration, irreversibility, and egocentrism.

❚ During the concrete operational period, children develop the ability to perform operations on mental representations, making them capable of conservation and hierarchical classification. The stage of formal operations ushers in more abstract, systematic, and logical thought.

❚ Vygotsky's sociocultural theory maintains that cognitive development is fueled by social interactions with parents and others. Vygotsky argued that language is central to cognitive development and that culture exerts great influence over how cognitive growth unfolds.

❚ Recent research has shown that infants appear to understand surprisingly complex concepts, including numerical operations that they have had virtually no opportunity to learn about, leading some theorists to conclude that basic cognitive abilities are innate.

❚ According to Kohlberg, moral reasoning progresses through three levels that are related to age and determined by cognitive development. Age-related progress in moral reasoning has been found in research, although a great deal of overlap occurs between adjacent stages.

The Transition of Adolescence

❚ The growth spurt at puberty is a prominent event involving the development of reproductive maturity and secondary sex characteristics. Neural development continues through adolescence and the prefrontal cortex appears to be the last area of the brain to fully mature. Adolescents' risk taking may be elevated by their susceptibility to peer influence.

❚ Recent decades have brought a surge in attempted suicide by adolescents. Nonetheless, the evidence suggests that adolescence is only slightly more stressful than other periods of life. According to Erikson, the key challenge of adolescence is to make some progress toward a sense of identity. Marcia identified four patterns of identity formation. Arnett has argued that emerging adulthood represents a new stage of development falling between adolescence and adulthood.

The Expanse of Adulthood

❚ During adulthood, personality is marked by both stability and change. Many landmarks in adult development involve transitions in family relationships, including adjusting to marriage, parenthood, and the empty nest. During adulthood, age-related physical transitions include changes in appearance, sensory losses, and hormonal changes.

❚ Research suggests that fluid intelligence declines in later adulthood, but crystallized intelligence tends to remain stable. Drastic mental decline is not a part of the normal aging process. However, many adults over age 75 suffer from some form of dementia. In late adulthood, mental speed declines and working memory suffers, but many people remain productive well into old age.

Reflecting on the Chapter's Themes

❚ Many of our seven integrative themes stood out in this chapter. But above all else, our discussion of development showed how heredity and environment interactively shape behavior.

PERSONAL APPLICATION Understanding Gender Differences

❚ Gender differences in behavior are fewer in number and smaller in magnitude than gender stereotypes suggest. Research reviews suggest that there are genuine (albeit small) gender differences in verbal ability, mathematical ability, spatial ability, aggression, nonverbal communication, and sexual behavior.

❚ Evolutionary theorists believe that gender differences reflect the influence of natural selection. Some research links gender differences in humans to prenatal hormones and brain organization, but the research is marred by interpretive problems. Operant conditioning, observational learning, and self-socialization contribute to the development of gender differences.

CRITICAL THINKING APPLICATION Are Fathers Essential to Children's Well-Being?

❚ Some social scientists have argued that father absence is the chief cause of a host of social problems and that fathers are essential for normal, healthy development. Critics have argued that there are alternative explanations for the association between father absence and negative developmental outcomes.

Key People

Mary Ainsworth (pp. 449–450)
John Bowlby (p. 449)
Erik Erikson (pp. 451–453)
Harry Harlow (p. 449)
Jerome Kagan (p. 448)
Lawrence Kohlberg (pp. 460–462)
Jean Piaget (pp. 453–457)
Alexander Thomas and Stella Chess (pp. 446–448)
Lev Vygotsky (pp. 457–457)

1. The stage of prenatal development during which the developing organism is most vulnerable to injury is the:
   A. zygotic stage.　　C. embryonic stage.
   B. germinal stage.　　D. fetal stage.

2. The cephalocaudal trend in the motor development of children can be described simply as a:
   A. head-to-foot direction.
   B. center-outward direction.
   C. foot-to-head direction.
   D. body-appendages direction.

3. Developmental norms:
   A. can be used to make extremely precise predictions about the age at which an individual child will reach various developmental milestones.
   B. indicate the maximum age at which a child can reach a particular developmental milestone and still be considered "normal."
   C. indicate the average age at which individuals reach various developmental milestones.
   D. involve both a and b.

4. When the development of the same subjects is studied over a period of time, the study is called a:
   A. cross-sectional study.　　C. longitudinal study.
   B. life history study.　　D. sequential study.

5. The quality of infant-caregiver attachment depends:
   A. on the quality of bonding in the first few hours of life.
   B. exclusively on the infant's temperament.
   C. on the interaction between the infant's temperament and the caregiver's responsiveness.
   D. on how stranger anxiety is handled.

6. During the second year of life, toddlers begin to take some personal responsibility for feeding, dressing, and bathing themselves in an attempt to establish what Erikson calls a sense of:
   A. superiority.
   B. industry.
   C. generativity.
   D. autonomy.

7. Five-year-old David watches as you pour water from a short, wide glass into a tall, narrow one. He says there is now more water than before. This response demonstrates that:
   A. David understands the concept of conservation.
   B. David does not understand the concept of conservation.
   C. David's cognitive development is "behind" for his age.
   D. both b and c are the case.

8. Which of the following is *not* one of the criticisms of Piaget's theory of cognitive development?
   A. Piaget may have underestimated the cognitive skills of children in some areas.
   B. Piaget may have underestimated the influence of cultural factors on cognitive development.
   C. The theory does not clearly address the issue of individual differences in development.
   D. Evidence for the theory is based on children's answers to questions.

9. If a child's primary reason for not drawing pictures on the living room wall with crayons is to avoid the punishment that would inevitably follow this behavior, she would be said to be at which level of moral development?
   A. conventional　　C. preconventional
   B. postconventional　　D. unconventional

10. The portion of the brain that appears to be the last area to mature fully is the:
    A. hypothalamus.　　C. prefrontal cortex.
    B. corpus callosum.　　D. occipital lobe.

11. Girls who mature _____ and boys who mature _____ seem to experience more subjective distress and emotional difficulties with the transition to adolescence.
    A. early; early
    B. early; late
    C. late; early
    D. late; late

12. Sixteen-year-old Foster wants to spend a few years experimenting with different lifestyles and careers before he settles on who and what he wants to be. Foster's behavior illustrates the identity status of:
    A. identity moratorium.　　C. identity achievement.
    B. identity foreclosure.　　D. identity diffusion.

13. Although women perform about _____ of all housework, about _____ of wives characterize their household division of labor as unfair.
    A. one-half; one-half
    B. two-thirds; three-quarters
    C. two-thirds; one-third
    D. three-quarters; one-tenth

14. Males have been found to differ slightly from females in three well-documented areas of mental abilities. Which of the following is *not* one of these?
    A. verbal ability　　C. intelligence
    B. mathematical ability　　D. visual-spatial abilities

15. Research suggests that males exhibit _____ than females and that females have a _____ than males.
    A. less cerebral specialization; smaller corpus callosum
    B. less cerebral specialization; larger corpus callosum
    C. more cerebral specialization; smaller corpus callosum
    D. more cerebral specialization; larger corpus callosum

Personality: Theory, Research, and Assessment

Richard Branson was sure that he was about to die. He was high above the Atlantic Ocean, alone in a capsule attached to the biggest balloon in the world. Per Lindstrand, the balloon's pilot, was somewhere in the icy waves far below. He and Branson had just become the first people ever to cross the Atlantic in a hot-air balloon, but when an emergency landing at sea failed, Lindstrand had leaped into the water. Before Branson could follow, the balloon had shot back up into the sky. Now Branson—who had never flown in a balloon before his all-too-brief training for the trip—was stranded in midair with no clear idea how to save himself.

Hastily Branson scribbled a note to his family: "I love you." Then he began trying to vent the huge balloon in a desperate attempt to guide it safely earthward. Much to his own surprise, he was able to get close enough to the sea to jump for it. A rescue helicopter plucked him out of the waves. (Lindstrand was saved by a passing fisherman.)

After this frightening brush with death, Branson swore that he would never risk his life so foolishly again. Yet three years later, he and Lindstrand were at it again, this time becoming the first to cross the Pacific in a hot-air balloon. The trip turned into an-

other terrifying ordeal—at one point the balloon caught fire when they were thousands of feet above empty ocean—and once again they were nearly killed. But that didn't stop them from planning their next exploit—trying to become the first hot-air balloonists to fly completely around the world (Branson, 2005; Brown, 1998).

What kind of person has such an insatiable hunger for death-defying adventures? When people describe this side of Richard Branson, they are apt to use words such as *adventurous, brave, daring, impulsive,* and *reckless.* These are the kinds of words used to characterize what we call "personality." And Branson—a self-made billionaire and one of the richest people in the world—may be as famous for his exuberant personality as he is for his immense wealth.

A high school dropout, Branson is the founder of the Virgin group of companies. Among Virgin's 200 businesses are such varied enterprises as Virgin Megastores, the airline Virgin Atlantic, and Virgin Galactic, which aims to become the first company to fly tourists into space. Branson is a brash, shrewd, and relentless entrepreneur who loves cutting a deal. But he also loves parties, practical jokes, and flamboyant publicity stunts. Most of all, he relishes finding

Richard Branson, the founder of the Virgin group of companies, clearly manifests a powerful and unusual personality. But everyone has his or her own unique personality, which makes the study of personality a fascinating area of inquiry in psychology.

© Michael Buckner/Getty Images

new fields to conquer. It was typical of Branson—who made his first fortune with a music recording company—to decide that it would be "fun" to start an airline even though he had no knowledge of the business, let alone routes to fly or planes to fly them (Branson, 2005; Brown, 1998). His approach is nicely summed up in the title of his book of life lessons, *Screw It, Let's Do It* (Branson, 2006).

Most people would agree that Richard Branson has an unusual personality. But what exactly *is* personality? And why are personalities so different? Why is one person daring, while another is timid? Why is one person high-spirited and outgoing, while another is quiet and shy? Was Richard Branson born with the self-confidence and daring he is renowned for, or were environment and learning critical in shaping his personality? Consider that Branson's parents stressed the importance of being strong and independent, starting at an early age. When Branson was just 4 years old, he relates, his mother "stopped the car a few miles from our house and made me find my own way home across the fields" (Branson, 2005, p. 15). Branson believes that episodes like these nurtured his enduring appe-

tite for "huge, apparently unachievable challenges" (Branson, 2005, p. 219).

Yet can this be the whole explanation? After all, another 4-year-old might have simply sat down by the road and cried. Could part of the answer to the riddle of Branson's personality lie in biological inheritance? Branson (2005) describes his mother as a woman of dazzling energy and fierce determination who also has a taste for adventure. During World War II Eve Branson wanted to be a glider pilot even though the job was open only to males. Refusing to take no for an answer, she talked her way into pilot training on the condition that she disguise herself as a boy. Branson's father, Ted, is a quieter sort who nevertheless shares his wife's adventurousness. When Branson dreamed up the idea for Virgin Galactic, an airline offering suborbital spaceflights, Ted said that he intended to be one of the first passengers launched into space—at the age of 90! With parents like these, is being an "adrenaline junkie" wired into Branson's genetic makeup?

Psychologists have approached questions like these from a variety of perspectives. Traditionally, the study of personality has been dominated by "grand theories" that attempt to explain a great many facets of behavior. Our discussion will reflect this emphasis, as we'll devote most of our time to the sweeping theories of Freud, Skinner, Rogers, and several others. In recent decades, however, the study of personality has shifted toward narrower research programs that examine specific issues related to personality. This trend is reflected in our review of biological, cultural, and other contemporary approaches to personality in the last several sections of the chapter. In the Personal Application, we'll examine how psychological tests are used to measure aspects of personality. The Critical Thinking Application will explore how hindsight bias can taint people's analyses of personality.

The Nature of Personality

Personality is a complex hypothetical construct that has been defined in a variety of ways. Let's take a closer look at the concepts of personality and personality traits.

Defining Personality: Consistency and Distinctiveness

What does it mean to say that someone has an optimistic personality? This assertion indicates that the

person has a fairly *consistent tendency* to behave in a cheerful, hopeful, enthusiastic way, looking at the bright side of things, across a wide variety of situations. Although no one is entirely consistent in behavior, this quality of *consistency across situations* lies at the core of the concept of personality.

Distinctiveness is also central to the concept of personality. Personality is used to explain why not everyone acts the same way in similar situations. If you were stuck in an elevator with three people, each might

react differently. One might crack jokes to relieve the tension. Another might make ominous predictions that "we'll never get out of here." The third might calmly think about how to escape. These varied reactions to the same situation occur because each person has a different personality. Each person has traits that are seen in other people, but each individual has his or her own distinctive *set* of personality traits.

In summary, the concept of personality is used to explain (1) the stability in a person's behavior over time and across situations (consistency) and (2) the behavioral differences among people reacting to the same situation (distinctiveness). We can combine these ideas into the following definition: *Personality refers to an individual's unique constellation of consistent behavioral traits.* Let's look more closely at the concept of *traits*.

Personality Traits: Dispositions and Dimensions

Everyone makes remarks like "Jan is very *conscientious.*" Or you might assert that "Bill is too *timid* to succeed in that job." These descriptive statements refer to personality traits. *A personality trait is a durable disposition to behave in a particular way in a variety of situations.* Adjectives such as *honest, dependable, moody, impulsive, suspicious, anxious, excitable, domineering,* and *friendly* describe dispositions that represent personality traits.

Most approaches to personality assume that some traits are more basic than others. According to this notion, a small number of fundamental traits determine other, more superficial traits. For example, a person's tendency to be impulsive, restless, irritable,

boisterous, and impatient might all be derived from a more basic tendency to be excitable.

A number of psychologists have taken on the challenge of identifying the basic traits that form the core of personality. For example, Raymond Cattell (1950, 1966, 1990) used the statistical procedure of *factor analysis* to reduce a list of 171 personality traits compiled by Gordon Allport (1937) to just 16 basic dimensions of personality. In *factor analysis, correlations among many variables are analyzed to identify closely related clusters of variables* (see Chapter 9). If the measurements of a number of variables (in this case, personality traits) correlate highly with one another, the assumption is that a single factor is influencing all of them. Factor analysis is used to identify these hidden factors. In factor analyses of personality traits, these hidden factors are viewed as basic, higher-order traits that determine less basic, more specific traits. Based on his factor analytic work, Cattell concluded that an individual's personality can be described completely by measuring just 16 traits. The 16 crucial traits are listed in **Figure 12.20**, which can be found in the Personal Application, where we discuss a personality test that Cattell designed to assess these traits.

The Five-Factor Model of Personality Traits

In recent years, Robert McCrae and Paul Costa (1987, 1997, 1999, 2003) have used factor analysis to arrive at an even simpler, *five-factor model of personality* (see **Figure 12.1**). McCrae and Costa maintain that most personality traits are derived from just five higher-order traits that have come to be known as the "Big Five":

Factor	Characteristics
Neuroticism (negative emotionality)	Worried versus calm Insecure versus secure Self-pitying versus self-satisfied
Extraversion (positive emotionality)	Sociable versus retiring Fun-loving versus sober Affectionate versus reserved
Openness to experience	Imaginative versus down-to-earth Preference for variety versus preference for routine Independent versus conforming
Agreeableness	Softhearted versus ruthless Trusting versus suspicious Helpful versus uncooperative
Conscientiousness (constraint)	Well organized versus disorganized Careful versus careless Self-disciplined versus weak willed

Figure 12.1
The five-factor model of personality. Trait models attempt to analyze personality into its basic dimensions. In factor-analytic studies, the five traits shown here tend to emerge as higher-order factors that can account for other traits. McCrae and Costa (1985, 1987, 1997) maintain that personality can be described adequately by scores on the five traits identified here, which are widely referred to as the Big Five.

SOURCE: Trait descriptions from McCrae, R. R., & Costa, P. T. (1986). Clinical assessment can benefit from recent advances in personality psychology. *American Psychologist, 41,* 1001–1003.

1. *Extraversion.* People who score high in extraversion are characterized as outgoing, sociable, upbeat, friendly, assertive, and gregarious. Referred to as *positive emotionality* in some trait models, extraversion has been studied extensively for many decades (Watson & Clark, 1997). Extraverts tend to be happier than others (Fleeson, Malanos, & Achille, 2002).

2. *Neuroticism.* People who score high in neuroticism tend to be anxious, hostile, self-conscious, insecure, and vulnerable. Like extraversion, this trait has been the subject of thousands of studies. In some trait models it is called *negative emotionality.* Those who score high in neuroticism tend to overreact more than others in response to stress (Mroczek & Almeida, 2004).

3. *Openness to experience.* Openness is associated with curiosity, flexibility, vivid fantasy, imaginativeness, artistic sensitivity, and unconventional attitudes. McCrae (1996) maintains that its importance has been underestimated. Citing evidence that openness fosters liberalism, he argues that this trait is the key determinant of people's political attitudes and ideology. For example, evidence suggests that people high in openness tend to exhibit less prejudice against minorities than others (Flynn, 2005).

4. *Agreeableness.* Those who score high in agreeableness tend to be sympathetic, trusting, cooperative, modest, and straightforward. People who score at the opposite end of this personality dimension are characterized as suspicious, antagonistic, and aggressive. Agreeableness is associated with constructive approaches to conflict resolution, making agreeable people less quarrelsome than others (Jensen-Campbell & Graziano, 2001).

5. *Conscientiousness.* Conscientious people tend to be disciplined, well organized, punctual, and dependable. Referred to as *constraint* in some trait models, conscientiousness is associated with being highly diligent in the workplace (Lund et al., 2007).

Research shows that Big Five traits are predictive of specific aspects of behavior, as one would expect (Paunonen, 2003). For example, extraversion correlates positively with popularity and with dating a greater variety of people. Conscientiousness correlates with greater honesty, higher job performance ratings, and relatively low alcohol consumption. Openness to experience is associated with playing a musical instrument, whereas agreeableness correlates with honesty.

Correlations have also been found between the Big Five traits and quite a variety of important life outcomes (Ozer & Benet-Martinez, 2006). For instance, higher grades (GPA) in both high school and college are associated with higher conscientiousness, primarily because conscientious students work harder (Noftle & Robins, 2007). Several of the Big Five traits are associated with occupational attainment (career success). Extraversion and conscientiousness are positive predictors of occupational attainment, whereas neuroticism is a negative predictor (Roberts, Caspi, & Moffitt, 2003). The likelihood of divorce can also be predicted by personality traits, as neuroticism elevates the probability of divorce, whereas agreeableness and conscientiousness reduce it (Roberts et al., 2007). Finally, and perhaps most important, two of the Big Five traits are related to health and mortality over the course of the life span. Neuroticism is associated with an elevated prevalence of physical and mental disorders, whereas conscientiousness is correlated with the experience of less illness and with reduced mortality (Goodwin & Friedman, 2006; Martin, Friedman, & Schwartz, 2007). In other words, conscientious people live longer than others!

Like Cattell, McCrae and Costa maintain that personality can be described adequately by measuring the basic traits that they've identified. Their bold claim has been supported in many studies by other researchers, and the five-factor model has become the dominant conception of personality structure in contemporary psychology (John & Srivastava, 1999; McCrae, 2005). These five traits have been characterized as the "latitude and longitude" along which personality should be mapped (Ozer & Reise, 1994, p. 361).

However, some theorists have been critical of the model. Jack Block (1995) has questioned the generality of the model. He points out that the higher-order traits that emerge in factor analyses depend to some extent on the exact mix of the much larger set of lower-order traits that are measured in the first place. Thus, he asserts that the five-factor model is more arbitrary than widely appreciated. Other critics of the five-factor model maintain that more than five traits are necessary to account for most of the variation seen in human personality. For example, one recent article argued that honesty-humility ought to be recognized as a fundamental sixth factor in personality (Ashton, Lee, & Goldberg, 2004). And other theorists have argued that there are some important traits—such as being manipulative, frugal, conservative, humorous, and egotistical—that do not fit into the five-factor model (Paunonen & Jackson, 2000).

The debate about how many dimensions are necessary to describe personality is likely to continue for many years to come. As you'll see throughout the chapter, the study of personality is an area in psychology that has a long history of "dueling theories." We'll divide these diverse personality theories

into four broad groups that share certain assumptions, emphases, and interests: (1) psychodynamic perspectives, (2) behavioral perspectives, (3) humanistic perspectives, and (4) biological perspectives. We'll begin our discussion of personality theories by examining the life and work of Sigmund Freud.

Psychodynamic Perspectives

Psychodynamic theories **include all the diverse theories descended from the work of Sigmund Freud, which focus on unconscious mental forces.** Freud inspired many brilliant scholars who followed in his intellectual footsteps. Some of these followers simply refined and updated Freud's theory. Others veered off in new directions and established independent, albeit related, schools of thought. Today, the psychodynamic umbrella covers a large collection of loosely related theories that we can only sample from in this text. In this chapter, we'll examine the ideas of Sigmund Freud in some detail. Then we'll take a briefer look at the psychodynamic theories of Carl Jung and Alfred Adler.

Freud's Psychoanalytic Theory

PSYK TREK 10a

Born in 1856, Sigmund Freud grew up in a middle-class Jewish home in Vienna, Austria. He showed an early interest in intellectual pursuits and became an intense, hardworking young man, driven to achieve fame. He experienced his share of inner turmoil and engaged in regular self-analysis for over 40 years. Freud lived in the Victorian era, which was marked by sexual repression. His life was also affected by the first great World War, which devastated Europe, and by the growing anti-Semitism of the times. We'll see that the sexual repression and aggressive hostilities that Freud witnessed left their mark on his view of human nature.

Freud was a physician specializing in neurology when he began his medical practice in Vienna toward the end of the 19th century. Like other neurologists in his era, he often treated people troubled by nervous problems such as irrational fears, obses-

sions, and anxieties. Eventually he devoted himself to the treatment of mental disorders using an innovative procedure he had developed, called *psychoanalysis,* that required lengthy verbal interactions with patients during which Freud probed deeply into their lives.

Freud's (1901, 1924, 1940) *psychoanalytic theory* grew out of his decades of interactions with his clients in psychoanalysis. Psychoanalytic theory attempts to explain personality, motivation, and psychological disorders by focusing on the influence of early childhood experiences, on unconscious motives and conflicts, and on the methods people use to cope with their sexual and aggressive urges.

Most of Freud's contemporaries were uncomfortable with his theory for at least three reasons. First, in arguing that people's behavior is governed by unconscious factors of which they are unaware, Freud made the disconcerting suggestion that individuals are not masters of their own minds. Second, in claiming that adult personalities are shaped by childhood experiences and other factors beyond one's control, he suggested that people are not masters of their own destinies. Third, by emphasizing the great importance of how people cope with their sexual urges, he offended those who held the conservative, Victorian values of his time. Let's examine the ideas that generated so much controversy.

Structure of Personality

PSYK TREK 10a

Freud divided personality structure into three components: the id, the ego, and the superego (see **Figure 12.2** on the next page). He saw a person's behavior as the outcome of interactions among these three components.

Sigmund Freud

"No one who, like me, conjures up the most evil of those half-tamed demons that inhabit the human beast, and seeks to wrestle with them, can expect to come through the struggle unscathed."

© National Library of Medicine

by behaving "properly." It also attempts to achieve long-range goals that sometimes require putting off gratification.

While the ego concerns itself with practical realities, the ***superego*** **is the moral component of personality that incorporates social standards about what represents right and wrong.** Throughout their lives, but especially during childhood, people receive training about what constitutes good and bad behavior. Many social norms regarding morality are eventually internalized. The superego emerges out of the ego at around 3 to 5 years of age. In some people, the superego can become irrationally demanding in its striving for moral perfection. Such people are plagued by excessive feelings of guilt. According to Freud, the id, ego, and superego are distributed differently across three levels of awareness, which we'll describe next.

Levels of Awareness

Perhaps Freud's most enduring insight was his recognition of how unconscious forces can influence behavior. He inferred the existence of the unconscious from a variety of observations that he made with his patients. For example, he noticed that "slips of the tongue" often revealed a person's true feelings. He also realized that his patients' dreams often expressed hidden desires. Most important, through psychoanalysis he often helped patients discover feelings and conflicts of which they had previously been unaware.

Freud contrasted the unconscious with the conscious and preconscious, creating three levels of awareness. **The *conscious* consists of whatever one is aware of at a particular point in time.** For example, at this moment your conscious may include the train of thought in this text and a dim awareness in the back of your mind that your eyes are getting tired and you're beginning to get hungry. **The *preconscious* contains material just beneath the surface of awareness that can easily be retrieved.** Examples might include your middle name, what you had for supper last night, or an argument you had with a friend yesterday. **The *unconscious* contains thoughts, memories, and desires that are well below the surface of conscious awareness but that nonetheless exert great influence on behavior.** Examples of material that might be found in your unconscious include a forgotten trauma from childhood, hidden feelings of hostility toward a parent, and repressed sexual desires.

Freud's conception of the mind is often compared to an iceberg that has most of its mass hidden beneath the water's surface (see **Figure 12.2**). He

Figure 12.2

Freud's model of personality structure. Freud theorized that people have three levels of awareness: the conscious, the preconscious, and the unconscious. The enormous size of the unconscious is often dramatized by comparing it to the portion of an iceberg that lies beneath the water's surface. Freud also divided personality structure into three components—id, ego, and superego—which operate according to different principles and exhibit different modes of thinking. In Freud's model, the id is entirely unconscious, but the ego and superego operate at all three levels of awareness.

The ***id*** **is the primitive, instinctive component of personality that operates according to the pleasure principle.** Freud referred to the id as the reservoir of psychic energy. By this he meant that the id houses the raw biological urges (to eat, sleep, defecate, copulate, and so on) that energize human behavior. The id operates according to the ***pleasure principle,*** **which demands immediate gratification of its urges.** The id engages in *primary-process thinking,* which is primitive, illogical, irrational, and fantasy oriented.

The ***ego*** **is the decision-making component of personality that operates according to the reality principle.** The ego mediates between the id, with its forceful desires for immediate satisfaction, and the external social world, with its expectations and norms regarding suitable behavior. The ego considers social realities—society's norms, etiquette, rules, and customs—in deciding how to behave. The ego is guided by the ***reality principle,*** **which seeks to delay gratification of the id's urges until appropriate outlets and situations can be found.** In short, to stay out of trouble, the ego often works to tame the unbridled desires of the id.

In the long run, the ego wants to maximize gratification, just as the id does. However, the ego engages in *secondary-process thinking,* which is relatively rational, realistic, and oriented toward problem solving. Thus, the ego strives to avoid negative consequences from society and its representatives (for example, punishment by parents or teachers)

believed that the unconscious (the mass below the surface) is much larger than the conscious or preconscious. As you can see in **Figure 12.2**, he proposed that the ego and superego operate at all three levels of awareness. In contrast, the id is entirely unconscious, expressing its urges at a conscious level through the ego. Of course, the id's desires for immediate satisfaction often trigger internal conflicts with the ego and superego. These conflicts play a key role in Freud's theory.

Conflict and the Tyranny of Sex and Aggression

Freud assumed that behavior is the outcome of an ongoing series of internal conflicts. He saw internal battles between the id, ego, and superego as routine. Why? Because the id wants to gratify its urges immediately, but the norms of civilized society frequently dictate otherwise. For example, your id might feel an urge to clobber a co-worker who constantly irritates you. However, society frowns on such behavior, so your ego would try to hold this urge in check. Hence, you would find yourself in conflict. You may be experiencing conflict at this very moment. In Freudian terms, your id may be secretly urging you to abandon reading this chapter so that you can fix a snack and watch some television. Your ego may be weighing this appealing option against your society-induced need to excel in school.

Freud believed that people's lives are dominated by conflict. He asserted that individuals careen from one conflict to another. The following scenario provides a concrete illustration of how the three components of personality interact to create constant conflicts:

Imagine lurching across your bed to shut off your alarm clock as it rings obnoxiously. It's 7 A.M. and time to get up for your history class. However, your id (operating according to the pleasure principle) urges you to return to the immediate gratification of additional sleep. Your ego (operating according to the reality principle) points out that you really must go to class since you haven't been able to decipher the textbook on your own. Your id (in its typical unrealistic fashion) smugly assures you that you will get the A grade that you need and suggests lying back to dream about how impressed your roommates will be. Just as you're relaxing, your superego jumps into the fray. It tries to make you feel guilty about all the money your parents paid in tuition for the class that you're about to skip. You haven't even gotten out of bed yet, but there's already a pitched battle in your psyche.

Not all conflicts are equal. Freud believed that conflicts centering on sexual and aggressive impulses are especially likely to have far-reaching con-

sequences. Why did he emphasize sex and aggression? Two reasons were prominent in his thinking. First, he thought that sex and aggression are subject to more complex and ambiguous social controls than other basic motives. The norms governing sexual and aggressive behavior are subtle, and people often get inconsistent messages about what's appropriate. Thus, Freud believed that these two drives are the source of much confusion. Second, he noted that the sexual and aggressive drives are thwarted more regularly than other basic biological urges. Think about it: If you get hungry or thirsty, you can simply head for a nearby vending machine or a drinking fountain. But if a department store clerk infuriates you, you aren't likely to reach across the counter and slug him or her. Likewise, when you see a person who inspires lustful urges, you don't normally walk up and propose a tryst in a nearby broom closet. There's nothing comparable to vending machines or drinking fountains for the satisfaction of sexual and aggressive urges. Freud ascribed great importance to these needs because social norms dictate that they be routinely frustrated.

Anxiety and Defense Mechanisms

Most internal conflicts are trivial and are quickly resolved one way or the other. Occasionally, however, a conflict will linger for days, months, or even years, creating internal tension. More often than not, such prolonged and troublesome conflicts involve sexual and aggressive impulses that society wants to tame. These conflicts are often played out entirely in the unconscious. Although you may not be aware of these unconscious battles, they can produce *anxiety*

Freud's psychoanalytic theory was based on decades of clinical work. He treated a great many patients in the consulting room pictured here. The room contains numerous artifacts from other cultures—and the original psychoanalytic couch.

"ALL I WANT FROM THEM IS A SIMPLE MAJORITY ON THINGS."

Figure 12.3
Freud's model of personality dynamics. According to Freud, unconscious conflicts between the id, ego, and superego sometimes lead to anxiety. This discomfort may lead to the use of defense mechanisms, which may temporarily relieve anxiety.

that slips to the surface of conscious awareness. The anxiety can be attributed to your ego worrying about (1) the id getting out of control and doing something terrible that leads to severe negative consequences or (2) the superego getting out of control and making you feel guilty about a real or imagined transgression.

The arousal of anxiety is a crucial event in Freud's theory of personality functioning (see **Figure 12.3**). Anxiety is distressing, so people try to rid themselves of this unpleasant emotion any way they can. This effort to ward off anxiety often involves the use of defense mechanisms. *Defense mechanisms* **are largely unconscious reactions that protect a person from unpleasant emotions such as anxiety and guilt** (see **Table 12.1**). Typically, they're mental maneuvers that work through self-deception. Consider *rationalization,* **which is creating false but plausible excuses to justify unacceptable behavior.** For example, after cheating someone in a business transaction, you might reduce your guilt by rationalizing that "everyone does it."

Characterized as "the flagship in the psychoanalytic fleet of defense mechanisms" (Paulhus, Fridhandler, & Hayes, 1997), repression is the most basic and widely used defense mechanism. *Repression* **is keeping distressing thoughts and feelings buried in the unconscious.** People tend to repress desires that make them feel guilty, conflicts that make them anxious, and memories that are painful. Repression

has been called "motivated forgetting." If you forget a dental appointment or the name of someone you don't like, repression may be at work.

Self-deception can also be seen in projection and displacement. *Projection* **is attributing one's own thoughts, feelings, or motives to another.** Usually, the thoughts one projects onto others are thoughts that would make one feel guilty. For example, if lusting for a co-worker makes you feel guilty, you might attribute any latent sexual tension between the two of you to the *other person's* desire to seduce you. *Displacement* **is diverting emotional feelings (usually anger) from their original source to a substitute target.** If your boss gives you a hard time at work and you come home and slam the door, kick the couch, and scream at your spouse, you're displacing your anger onto irrelevant targets. Unfortunately, social constraints often force people to hold back their anger, and they end up lashing out at the people they love most.

Other prominent defense mechanisms include reaction formation, regression, and identification. *Reaction formation* **is behaving in a way that's exactly the opposite of one's true feelings.** Guilt about sexual desires often leads to reaction formation. For example, Freud theorized that many males who ridicule homosexuals are defending against their own latent homosexual impulses. The telltale sign of reaction formation is the exaggerated quality of the opposite behavior. *Regression* **is a reversion to immature patterns of behavior.** When anxious about their self-worth, some adults respond with childish boasting and bragging (as opposed to subtle efforts to impress others). For example, a fired executive having difficulty finding a new job might start making ridiculous statements about his incomparable talents and achievements. Such bragging is regressive when it's marked by massive exaggerations that virtually anyone can see through. *Identification* **is bolstering self-esteem by forming an imaginary or real alliance with some person or group.** Youngsters often shore up precarious feelings of self-worth by identifying with rock stars, movie stars, or famous athletes. Adults may join exclusive country clubs or civic organizations as a means of identification.

A great variety of theorists have made extensive additions to Freud's original list of defenses (Vaillant, 1992). We'll examine some of these additional defense mechanisms in the next chapter, when we discuss the role of defenses in coping with stress. For now, however, let's turn our attention to Freud's ideas about the development of personality.

Intrapsychic conflict (between id, ego, and superego) → Anxiety → Reliance on defense mechanisms

Table 12.1 Defense Mechanisms, with Examples

Defense Mechanism	Definition	Example
Repression	Keeping distressing thoughts and feelings buried in the unconscious	A traumatized soldier has no recollection of the details of a close brush with death.
Projection	Attributing one's own thoughts, feelings, or motives to another	A woman who dislikes her boss thinks she likes her boss but feels that the boss doesn't like her.
Displacement	Diverting emotional feelings (usually anger) from their original source to a substitute target	After parental scolding, a young girl takes her anger out on her little brother.
Reaction formation	Behaving in a way that is exactly the opposite of one's true feelings	A parent who unconsciously resents a child spoils the child with outlandish gifts.
Regression	A reversion to immature patterns of behavior	An adult has a temper tantrum when he doesn't get his way.
Rationalization	Creating false but plausible excuses to justify unacceptable behavior	A student watches TV instead of studying, saying that "additional study wouldn't do any good anyway."
Identification	Bolstering self-esteem by forming an imaginary or real alliance with some person or group	An insecure young man joins a fraternity to boost his self-esteem.

Note: See Table 13.2 for additional examples of defense mechanisms.

Development: Psychosexual Stages

10a

Freud believed that "the child is father to the man." In fact, he made the rather startling assertion that the basic foundation of an individual's personality has been laid down by the tender age of 5. To shed light on these crucial early years, Freud formulated a stage theory of development. He emphasized how young children deal with their immature but powerful sexual urges (he used the term *sexual* in a general way to refer to many urges for physical pleasure). According to Freud, these sexual urges shift in focus as children progress from one stage of development to another. Indeed, the names for the stages (oral, anal, genital, and so on) are based on where children are focusing their erotic energy during that

concept check 12.1

Identifying Defense Mechanisms

Check your understanding of defense mechanisms by identifying specific defenses in the story below. Each example of a defense mechanism is underlined, with a number beneath it. Write in the defense at work in each case in the numbered spaces after the story. The answers are in Appendix A.

My girlfriend recently broke up with me after we had dated seriously for several years. At first, I cried a great deal and locked myself in my room, where I pouted endlessly. [1] I was sure that my former girlfriend felt as miserable as I did. I told several friends that she was probably lonely and depressed. [2] Later, I decided that I hated her. I was happy about the breakup and talked about how much I was going to enjoy my newfound freedom. [3] I went to parties and socialized a great deal and just forgot about her. It's funny—at one point I couldn't even remember her phone number! [4] Then I started pining for her again. But eventually I began to look at the situation more objectively. I realized that she had many faults and that we were bound to break up sooner or later, so I was better off without her. [5]

2. _____   5. _____

3. _____

period. Thus, *psychosexual stages* are developmental periods with a characteristic sexual focus that leave their mark on adult personality.

Freud theorized that each psychosexual stage has its own unique developmental challenges or tasks (see Table 12.2). The way these challenges are handled supposedly shapes personality. The process of *fixation* plays an important role in this process. *Fixation is a failure to move forward from one stage to another as expected.* Essentially, the child's development stalls for a while. Fixation can be caused by *excessive gratification* of needs at a particular stage or by *excessive frustration* of those needs. Either way, fixations left over from childhood affect adult personality. Generally, fixation leads to an overemphasis on the psychosexual needs prominent during the fixated stage. Freud described a series of five psychosexual stages. Let's examine some of the highlights in this sequence.

Oral Stage.   This stage encompasses the first year of life. During this period, the main source of erotic stimulation is the mouth (in biting, sucking, chewing, and so on). In Freud's view, the way the child's feeding experiences is handled is crucial to subsequent development. He attributed considerable importance to the manner in which the child is weaned from the breast or the bottle. According to Freud, fixation at the oral stage could form the basis for obsessive eating or smoking later in life (among many other things).

Anal Stage.   In their second year, children get their erotic pleasure from their bowel movements, through either the expulsion or retention of feces. The crucial event at this time is toilet training, which represents society's first systematic effort to regulate the child's biological urges. Severely punitive toilet training leads to a variety of possible outcomes. For example, excessive punishment might produce a latent feeling of hostility toward the "trainer," usually the mother. This hostility might generalize to women as a class. Another possibility is that heavy reliance on punitive measures could lead to an as-

According to Freud, early childhood experiences such as toilet training (a parental attempt to regulate a child's biological urges) can influence an individual's personality, with consequences lasting throughout adulthood.

sociation between genital concerns and the anxiety that the punishment arouses. This genital anxiety derived from severe toilet training could evolve into anxiety about sexual activities later in life.

Phallic Stage.   Around age 4, the genitals become the focus for the child's erotic energy, largely through self-stimulation. During this pivotal stage, the *Oedipal complex* emerges. That is, little boys develop an erotically tinged preference for their mother. They also feel hostility toward their father, whom they view as a competitor for mom's affection. Similarly, little girls develop a special attachment to their fa-

Table 12.2 Freud's Stages of Psychosexual Development

Stage	Approximate Ages	Erotic Focus	Key Tasks and Experiences
Oral	0–1	Mouth (sucking, biting)	Weaning (from breast or bottle)
Anal	2–3	Anus (expelling or retaining feces)	Toilet training
Phallic	4–5	Genitals (masturbating)	Identifying with adult role models; coping with Oedipal crisis
Latency	6–12	None (sexually repressed)	Expanding social contacts
Genital	Puberty onward	Genitals (being sexually intimate)	Establishing intimate relationships; contributing to society through working

ther. Around the same time, they learn that little boys have different genitals and supposedly develop *penis envy.* According to Freud, young girls feel hostile toward their mother because they blame her for their anatomical "deficiency."

To summarize, **in the *Oedipal complex* children manifest erotically tinged desires for their opposite-sex parent, accompanied by feelings of hostility toward their same-sex parent.** The name for this syndrome was taken from a tragic myth from ancient Greece. In this story, Oedipus was separated from his parents at birth. Not knowing the identity of his real parents, when he grew up he inadvertently killed his father and married his mother.

According to Freud, the way parents and children deal with the sexual and aggressive conflicts inherent in the Oedipal complex is of paramount importance. The child has to resolve the Oedipal dilemma by purging the sexual longings for the opposite-sex parent and by crushing the hostility felt toward the same-sex parent. In Freud's view, healthy psychosexual development hinges on the resolution of the Oedipal conflict. Why? Because continued hostility toward the same-sex parent may prevent the child from identifying adequately with that parent. Freudian theory predicts that without such identification, sex typing, conscience, and many other aspects of the child's development won't progress as they should.

Latency and Genital Stages. From around age 6 through puberty, the child's sexuality is largely suppressed—it becomes *latent.* Important events during this *latency stage* center on expanding social contacts beyond the immediate family. With puberty, the child progresses into the *genital stage.* Sexual urges reappear and focus on the genitals once again. At this point, sexual energy is normally channeled toward peers of the other sex, rather than toward oneself as in the phallic stage.

In arguing that the early years shape personality, Freud did not mean that personality development comes to an abrupt halt in middle childhood. However, he did believe that the foundation for adult personality has been solidly entrenched by this time. He maintained that future developments are rooted in early, formative experiences and that significant conflicts in later years are replays of crises from childhood.

In fact, Freud believed that unconscious sexual conflicts rooted in childhood experiences cause most personality disturbances. His steadfast belief in the psychosexual origins of psychological disorders eventually led to bitter theoretical disputes with two of his most brilliant colleagues: Carl Jung and Alfred Adler. Jung and Adler both argued that Freud over-emphasized sexuality. Freud rejected their ideas, and the other two theorists felt compelled to go their own way, developing their own theories of personality.

Jung's Analytical Psychology

Carl Jung was born to middle-class Swiss parents in 1875. The son of a Protestant pastor, he was a deeply introverted, lonely child, but an excellent student. Jung had earned his medical degree and was an established young psychiatrist in Zurich when he began to write to Freud in 1906. When the two men had their first meeting, they were so taken by each other's insights, they talked nonstop for 13 hours! They exchanged 359 letters before their friendship and theoretical alliance were torn apart. Their relationship was ruptured irreparably in 1913 by a variety of theoretical disagreements.

Jung called his new approach *analytical psychology* to differentiate it from Freud's psychoanalytic theory. Jung's analytical psychology eventually attracted many followers. Perhaps because of his conflicts with Freud, Jung claimed to deplore the way schools of thought often become dogmatic, discouraging new ideas. Although many theorists came to characterize themselves as "Jungians," Jung himself often remarked, "I am not a Jungian" and said, "I do not want anybody to be a Jungian. I want people above all to be themselves" (van der Post, 1975).

Like Freud, Jung (1921, 1933) emphasized the unconscious determinants of personality. However, he proposed that the unconscious consists of two layers. The first layer, called the *personal unconscious,* is essentially the same as Freud's version of the unconscious. **The *personal unconscious* houses material that is not within one's conscious awareness because it has been repressed or forgotten.** In addition, Jung theorized the existence of a deeper layer he called the collective unconscious. **The *collective unconscious* is a storehouse of latent memory traces inherited from people's ancestral past.** According to Jung, each person shares the collective unconscious with the entire human race (see **Figure 12.4** on the next page). It contains the "whole spiritual heritage of mankind's evolution, born anew in the brain structure of every individual" (Jung, quoted in Campbell, 1971, p. 45).

Jung called these ancestral memories *archetypes.* They are not memories of actual, personal experiences. Instead, ***archetypes* are emotionally charged images and thought forms that have universal meaning.** These archetypal images and ideas show up frequently in dreams and are often manifested in a culture's use of symbols in art, literature, and religion. According to Jung, symbols from very different

Synchronicity, archetypes, collective unconscious, introversion, extraversion—these and many other important concepts arising from analytical psychology and Jung's tremendously influential theorizing are examined at this comprehensive site.

Figure 12.4

Jung's vision of the collective unconscious. Much like Freud, Jung theorized that each person has conscious and unconscious levels of awareness. However, he also proposed that the entire human race shares a collective unconscious, which exists in the deepest reaches of everyone's awareness. He saw the collective unconscious as a storehouse of hidden ancestral memories, called archetypes. Jung believed that important cultural symbols emerge from these universal archetypes. Thus, he argued that remarkable resemblances among symbols from disparate cultures (such as the mandalas shown here) are evidence of the existence of the collective unconscious.

cultures often show striking similarities because they emerge from archetypes that are shared by the whole human race. For instance, Jung found numerous cultures in which the *mandala,* or "magic circle," has served as a symbol of the unified wholeness of the self (see **Figure 12.4**). Jung felt that an understanding of archetypal symbols helped him make sense of his patients' dreams. This was of great concern to him, as he thought that dreams contain important messages from the unconscious. Like Freud, he depended extensively on dream analysis in his treatment of patients.

Adler's Individual Psychology

Like Freud, Alfred Adler grew up in Vienna in a middle-class Jewish home. He was a sickly child who struggled to overcome rickets (a vitamin-deficiency disease) and an almost fatal case of pneumonia. At home, he was overshadowed by an exceptionally bright and successful older brother. Nonetheless, he went on to earn his medical degree, and he practiced ophthalmology and general medicine before his interest turned to psychiatry. He was a charter member of Freud's inner circle—the Vienna Psychoanalytic Society. However, he soon began to develop his own theory of personality, perhaps because he didn't want

to be dominated once again by an "older brother" (Freud). His theorizing was denounced by Freud in 1911, and Adler was forced to resign from the Psychoanalytic Society. He took 9 of its 23 members with him to form his own organization. Adler's new approach to personality was christened *individual psychology.*

Like Jung, Adler (1917, 1927) argued that Freud had gone overboard in centering his theory on sexual conflicts. According to Adler, the foremost source of human motivation is a striving for superiority. In his view, this striving does not necessarily translate into the pursuit of dominance or high status. Adler saw ***striving for superiority* as a universal drive to adapt, improve oneself, and master life's challenges.** He noted that young children understandably feel weak and helpless in comparison with more competent older children and adults. These early inferiority feelings supposedly motivate them to acquire new skills and develop new talents. Thus, Adler maintained that striving for superiority is the prime goal of life, rather than physical gratification (as suggested by Freud).

Adler asserted that everyone has to work to overcome some feelings of inferiority—a process he called compensation. ***Compensation* involves efforts to overcome imagined or real inferiorities by developing one's abilities.** Adler believed that compen-
Alfred Adler

sation is entirely normal. However, in some people inferiority feelings can become excessive, resulting in what is widely known today as an *inferiority complex*—exaggerated feelings of weakness and inadequacy. Adler thought that either parental pampering or parental neglect could cause an inferiority complex. Thus, he agreed with Freud on the importance of early childhood experiences, although he focused on different aspects of parent-child relations.

Adler explained personality disturbances by noting that excessive inferiority feelings can pervert the normal process of striving for superiority. He asserted that some people engage in *overcompensation* to conceal, even from themselves, their feelings of inferiority. Instead of working to master life's challenges, people with an inferiority complex work to achieve status, gain power over others, and acquire the trappings of success (fancy clothes, impressive cars, or whatever looks important to them). They tend to flaunt their success in an effort to cover up their underlying inferiority complex. However, the problem is that such people engage in unconscious self-deception, worrying more about *appearances* than *reality*.

Adler's theory stressed the social context of personality development (Hoffman, 1994). For instance, it was Adler who first focused attention on the possible importance of *birth order* as a factor governing personality. He noted that first-borns, second children, and later-born children enter varied home environments and are treated differently by parents and that these experiences are likely to affect their personality. For example, he hypothesized that only children are often spoiled by excessive attention from parents and that first-borns are often problem children because they become upset when they're "dethroned" by a second child. Adler's theory stimulated hundreds of studies on the effects of birth order, but these studies generally failed to support his hypotheses and did not uncover any reliable correlations between birth order and personality (Ernst & Angst, 1983; J. R. Harris, 2000).

In recent years, however, Frank Sulloway (1995, 1996, 2007) has argued persuasively that birth order *does* have an impact on personality. Sulloway's reformulated hypotheses focus on how the Big Five traits are shaped by competition among siblings as they struggle to find a "niche" in their family environments. For example, he hypothesizes that first-borns should be more conscientious but less agreeable and open to experience than later-borns. In light of these personality patterns, he further speculates that first-borns tend to be conventional and achievement oriented, whereas later-borns tend to be liberal and rebellious. To evaluate his hypotheses, Sulloway reexamined decades of research on birth

Adler's theory has been used to analyze the tragic life of the legendary actress Marilyn Monroe (Ansbacher, 1970). During her childhood, Monroe suffered from parental neglect that left her with acute feelings of inferiority. Her inferiority feelings led her to overcompensate by flaunting her beauty, marrying celebrities (Joe DiMaggio and Arthur Miller), keeping film crews waiting for hours, and seeking the adoration of her fans.

order. After eliminating many studies that failed to control for important confounding variables, such as social class and family size, he concluded that the results of the remaining, well-controlled studies provided impressive evidence in favor of his hypotheses. Some subsequent studies have provided additional support for Sulloway's analyses (Beck, Burnet, & Vosper, 2006; Healy & Ellis, 2007; Rohde et al., 2003), but others have not (Freese, Powell, & Steelman, 1999; J. R. Harris, 2000; Skinner, 2003). More studies will be needed, as research on birth order is enjoying a bit of a renaissance.

Evaluating Psychodynamic Perspectives

The psychodynamic approach has provided a number of far-reaching, truly "grand" theories of personality. These theories yielded some bold new insights when they were first presented. Although one might argue about exact details of interpretation, research has demonstrated that (1) unconscious forces can influence behavior, (2) internal conflict often plays a key role in generating psychological distress, (3) early childhood experiences can have powerful influences on adult personality, and (4) people do use defense mechanisms to reduce their experience of unpleasant emotions (Bornstein, 2003; Solms, 2004; Westen, 1998; Westen & Gabbard, 1999).

In addition to being praised, psychodynamic formulations have also been criticized on several grounds, including the following (Crews, 2006; Eysenck, 1990b; Kramer, 2006; Torrey, 1992):

1. *Poor testability.* Scientific investigations require testable hypotheses. Psychodynamic ideas have often been too vague and conjectural to permit a clear scientific test. For instance, how would you prove or disprove the assertion that the id is entirely unconscious?

2. *Inadequate evidence.* The empirical evidence on psychodynamic theories has often been characterized as "inadequate." Psychodynamic theories depend too heavily on clinical case studies in which it's much too easy for clinicians to see what they expect to see. Reexaminations of Freud's own clinical work suggest that he frequently distorted his patients' case histories to make them mesh with his theory (Esterson, 2001; Powell & Boer, 1995). Insofar as researchers have accumulated evidence on psychodynamic theories, the evidence has provided only modest support for many of the central hypotheses (Fisher & Greenberg, 1985, 1996; Westen & Gabbard, 1999; Wolitzky, 2006).

3. *Sexism.* Many critics have argued that psychodynamic theories are characterized by a sexist bias against women. Freud believed that females' penis envy made them feel inferior to males. He also thought that females tended to develop weaker superegos and to be more prone to neurosis than males. The sex bias in modern psychodynamic theories has been reduced considerably. Nonetheless, the psychodynamic approach has generally provided a rather male-centered point of view (Lerman, 1986; Person, 1990).

It's easy to ridicule Freud for concepts such as penis envy, and it's easy to point to Freudian ideas that have turned out to be wrong. However, you have to remember that Freud, Jung, and Adler began to fashion their theories over a century ago. It's not entirely fair to compare these theories to other models that are only a decade or two old. That's like asking the Wright brothers to race a modern military jet. Freud and his colleagues deserve great credit for breaking new ground with their speculations about psychodynamics. In psychology as a whole, no other school of thought has been as influential, with the exception of behaviorism, to which we turn next.

Behavioral Perspectives

Behaviorism **is a theoretical orientation based on the premise that scientific psychology should study only observable behavior.** As we saw in Chapter 1, behaviorism has been a major school of thought in psychology since 1913, when John B. Watson began campaigning for the behavioral point of view. Research in the behavioral tradition has focused largely on learning. For many decades behaviorists devoted relatively little attention to the study of personality. However, their interest in personality began to pick up after John Dollard and Neal Miller (1950) attempted to translate selected Freudian ideas into behavioral terminology. Dollard and Miller showed that behavioral concepts could provide enlightening insights about the complicated subject of personality.

In this section, we'll examine three behavioral views of personality, as we discuss the ideas of B. F. Skinner, Albert Bandura, and Walter Mischel. For the most part, you'll see that behaviorists explain personality the same way they explain everything else—in terms of learning.

Skinner's Ideas Applied to Personality

PSYK TREK
10b

As we noted in Chapters 1 and 6, modern behaviorism's most prominent theorist has been B. F. Skin-

ner, an American psychologist who lived from 1904 to 1990. After earning his doctorate in 1931, Skinner spent most of his career at Harvard University. There he achieved renown for his research on the principles of learning, which were mostly discovered through the study of rats and pigeons. Skinner's (1953, 1957) concepts of *operant conditioning* were never meant to be a theory of personality. However, his ideas have affected thinking in all areas of psychology and have been applied to the explanation of personality. Here we'll examine Skinner's views as they relate to personality structure and development.

Personality Structure: A View from the Outside 10b

Skinner made no provision for internal personality structures similar to Freud's id, ego, and superego because such structures can't be observed. Following in the tradition of Watson's radical behaviorism, Skinner showed little interest in what goes on "inside" people. He argued that it's useless to speculate about private, unobservable cognitive processes. Instead, he focused on how the external environment molds overt behavior. Indeed, he argued for a strong brand of *determinism,* asserting that behavior is fully determined by environmental stimuli. He claimed that free will is but an illusion, saying, "There is no place in the scientific position for a self as a true originator or initiator of action" (Skinner, 1974, p. 225).

How can Skinner's theory explain the consistency that can be seen in individuals' behavior? According to his view, people show some consistent patterns of behavior because they have some stable *response tendencies* that they have acquired through experience. These response tendencies may change in the future, as a result of new experience, but they're enduring enough to create a certain degree of consistency in a person's behavior. Implicitly, then, Skinner viewed an individual's personality as a *collection of response tendencies that are tied to various stimulus situations.* A specific situation may be associated with a number of response tendencies that vary in strength, depending on past conditioning (see **Figure 12.5**).

Personality Development as a Product of Conditioning 10b

Skinner's theory accounts for personality development by explaining how various response tendencies are acquired through learning (Bolling, Terry, & Kohlenberg, 2006). He believed that most human responses are shaped by the type of conditioning that he described: operant conditioning. As discussed in Chapter 6, Skinner maintained that environmental consequences—reinforcement, punishment, and extinction—determine people's patterns of respond-

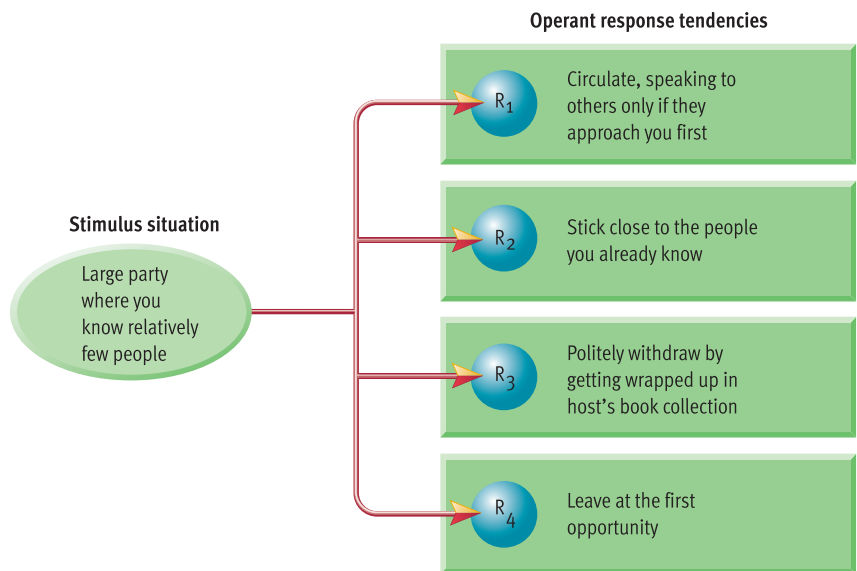
ing. On the one hand, when responses are followed by favorable consequences (reinforcement), they are strengthened. For example, if your joking at a party pays off with favorable attention, your tendency to joke at parties will increase (see **Figure 12.6**). On the


Figure 12.5
A behavioral view of personality. Staunch behaviorists devote little attention to the structure of personality because it is unobservable, but they implicitly view personality as an individual's collection of response tendencies. A possible hierarchy of response tendencies for a particular person in a specific stimulus situation (a large party) is shown here.

Figure 12.6
Personality development and operant conditioning. According to Skinner, people's characteristic response tendencies are shaped by reinforcers and other consequences that follow behavior. Thus, if your joking at a party leads to attention and compliments, your tendency to be witty and humorous will be strengthened.
B. F. Skinner
"The practice of looking inside the organism for an explanation of behavior has tended to obscure the variables which are immediately available for a scientific analysis. These variables lie outside the organism, in its immediate environment and in its environmental history.... The objection to inner states is not that they do not exist, but that they are not relevant."

other hand, when responses lead to negative consequences (punishment), they are weakened. Thus, if your impulsive decisions always backfire, your tendency to be impulsive will decline.

Because response tendencies are constantly being strengthened or weakened by new experiences, Skinner's theory views personality development as a continuous, lifelong journey. Unlike Freud and many other theorists, Skinner saw no reason to break the developmental process into stages. Nor did he attribute special importance to early childhood experiences.

Skinner believed that conditioning in humans operates much the same as it did in the rats and pigeons that he studied in his laboratory. Hence, he assumed that conditioning strengthens and weakens response tendencies "mechanically"—that is, without the person's conscious participation. Thus, Skinner was able to explain consistencies in behavior (personality) without being concerned about individuals' cognitive processes.

Skinner's ideas continue to be highly influential, but his mechanical, deterministic, noncognitive view of personality has not gone unchallenged by other behaviorists. In recent decades, several theorists have developed somewhat different behavioral models with a more cognitive emphasis.

Bandura's Social Cognitive Theory

10b

Albert Bandura is a modern theorist who has helped reshape the theoretical landscape of behaviorism. Bandura grew up in Canada and earned his doctorate in psychology at the University of Iowa. He has spent his entire academic career at Stanford University, where he has conducted influential research on behavior therapy and the determinants of aggression.

Cognitive Processes and Reciprocal Determinism

10b

Bandura is one of several theorists who have added a cognitive flavor to behaviorism since the 1960s. Bandura (1977), Walter Mischel (1973), and Julian Rotter (1982) take issue with Skinner's "pure" behaviorism. They point out that humans obviously are conscious, thinking, feeling beings. Moreover, these theorists argue that in neglecting cognitive processes, Skinner ignored the most distinctive and important feature of human behavior. Bandura and like-minded theorists originally called their modified brand of behaviorism *social learning theory*. Today, Bandura refers to his model as *social cognitive theory.*

Bandura (1986, 1999b) agrees with the fundamental thrust of behaviorism in that he believes that personality is largely shaped through learning. However, he contends that conditioning is not a mechanical process in which people are passive participants. Instead, he maintains that "people are self-organizing, proactive, self-reflecting, and self-regulating, not just reactive organisms shaped and shepherded by external events" (Bandura, 1999b, p. 154). Bandura (2001, 2006) also emphasizes the important role of forward-directed planning, noting that "people set goals for themselves, anticipate the likely consequences of prospective actions, and select and create courses of action likely to produce desired outcomes and avoid detrimental ones" (Bandura, 2001, p. 7).

Comparing his theory to Skinner's highly deterministic view, Bandura advocates a position called *reciprocal determinism.* According to this notion, the environment does determine behavior (as Skinner would argue). However, behavior also determines the environment. In other words, people can select their environments and act to alter them (by changing the friends they hang around with, for instance). Moreover, personal factors (cognitive structures such as beliefs and expectancies) determine and are determined by both behavior and the environment (see **Figure 12.7**). Thus, *reciprocal determinism* **is the idea that internal mental events, external environmental events, and overt behavior all influence one another.** According to Bandura, humans are neither masters of their own destiny nor hapless victims buffeted about by the environment. To some extent, people shape their environments, an observation that brings us to our Featured Study, which looked at how individuals mold their physical environments—and the clues that these environments can provide about personality.
Figure 12.7

Bandura's reciprocal determinism. Bandura rejects Skinner's highly deterministic view that behavior is governed by environment and that freedom is an illusion. Bandura argues that internal mental events, external environmental contingencies, and overt behavior all influence one another.

Albert Bandura

"Most human behavior is learned by observation through modeling."

Can Rooms *Really* Have Personality?

You may have heard someone comment that a particular house or specific room "has personality." This metaphor is usually intended to convey that the house or room is unusual or distinctive. But Bandura's point that people proactively choose and shape their environments raises the possibility that rooms could *literally* have personality—the personality of their occupants.

A variety of theories assert that individuals select and create their social and physical environments to match their dispositions and self-views. For example, people who choose formal or informal furniture or conventional versus unconventional decorating convey something about who they are, as do people who display an Amy Winehouse poster or photos of their travels. In places where they dwell, people also leave a *behavioral residue*—remnants of their activities, such as books, magazines, computer printouts, drawings, musical instruments, snacks, and discarded beer cans. Aware of these realities, Samuel Gosling and his colleagues set out to determine just how much observers can infer about an individual's personality based on visiting the person's office or bedroom. We will examine the study of offices in more detail and then summarize the results of the study of bedrooms.

Method

Occupants and observations. Ninety-four office occupants in five urban office buildings agreed to participate. Eight independent observers examined each participant's office and rated the occupant (who was not present) on a 44-item scale that assessed the Big Five personality traits. All photos of the occupants and references to their names were covered before the observers visited the offices. The intent was to see how ordinary people arrive at everyday impressions, so the observers had no special training or expertise.

Assessments of accuracy. To gauge the accuracy of the observers' personality inferences, the office occupants were asked to submit personality ratings of themselves and to suggest two peers who knew them well and who could also rate their personality (on the same 44-item scale used by the observers). The self-ratings and peer-ratings for each occupant were combined and then compared to the ratings made by the observers.

Results

Moderate positive correlations were found among the eight observers' personality ratings, indicating a reasonable consensus among them. Their combined ratings were then correlated with the self- and peer-ratings of the occupants. These correlations, which averaged .22, indicated that the observers were more accurate at judging some traits than others (see **Figure 12.8**). The assessments of the occupants' openness to experience were impressive, and the judgments of the occupants' extraversion, conscientiousness, and emotional stability were substantial.

Follow-Up Study

A second study, focusing on individuals' bedrooms rather than offices, was conducted using identical methods. The occupants were 83 college students or recent graduates living near a university in apartments, houses, and dormitories. Once again, reasonable consensus was found among the observers' personality ratings. However, the accuracy of the ratings based on people's bedrooms was noticeably higher (average correlation of .37) than it was for offices. As in the first study, the inferences about some traits were more accurate than others (see **Figure 12.8**), with ratings of openness to experience yielding the greatest accuracy.

Discussion

The authors conclude that "much can be learned about persons from the spaces in which they dwell" (p. 397) and that personal dwellings yield more valid cues for certain traits than for others. To put their findings in context, they note that on some personality traits, the room-based ratings

Figure 12.8

Accuracy of personality ratings based on people's rooms. To assess the accuracy of observers' personality ratings based on visiting people's offices or bedrooms, Gosling et al. (2002) correlated the observers' aggregated ratings with the combined self- and peer-ratings of the occupants of the rooms. Higher correlations are indicative of greater accuracy. If observers were not able to infer anything meaningful about occupants' personalities based on visiting their offices or bedrooms, these correlations would hover near zero, which was true in only one case (the ratings of agreeableness based on office visits). (Based on data from Gosling et al., 2002)
were more accurate than similar ratings from other studies that were based on long-term acquaintance! They speculate that bedrooms may be richer sources of information about their occupants than offices because people have more freedom to decorate bedrooms as they please and less need to project a professional image.

Comment

This study was featured because it took a creative approach to exploring an interesting phenomenon that has never before been subjected to scientific analysis. In retrospect, it seems readily apparent that people try to convey something about themselves in their dwellings and that visitors do form impressions based on these cues—but no one had previously thought to study these processes empirically. The creativity required to launch an entirely new line of research is apparent in one of its quirks: Who were the subjects? The occupants of the rooms? The observers who made the personality ratings? The participants in research are normally obvious—but in this case it is rather ambiguous. In any event, this study demonstrated that the relationship between personality and environment is a reciprocal one, as envisioned by Bandura.

Observational Learning

10b

Bandura's foremost theoretical contribution has been his description of observational learning, which we introduced in Chapter 6. *Observational learning* occurs when an organism's responding is influenced by the observation of others, who are called models. According to Bandura, both classical and operant conditioning can occur vicariously when one person observes another's conditioning. For example, watching your sister get cheated by someone giving her a bad check for her old stereo could strengthen your tendency to be suspicious of others. Although your sister would be the one actually experiencing the negative consequences, they might also influence you—through observational learning.

Bandura maintains that people's characteristic patterns of behavior are shaped by the *models* that they're exposed to. He isn't referring to the fashion models who dominate the mass media—although they do qualify. In observational learning, a *model is a person whose behavior is observed by another.* At one time or another, everyone serves as a model for others. Bandura's key point is that many response tendencies are the product of *imitation*.

As research has accumulated, it has become apparent that some models are more influential than others (Bandura, 1986). Both children and adults tend to imitate people they like or respect more than people they don't. People are also especially prone to imitate the behavior of people whom they consider attractive or powerful (such as rock stars). In addition, imitation is more likely when people see similarity between models and themselves. Thus, children tend to imitate same-sex role models somewhat more than opposite-sex models. Finally, people are more likely to copy a model if they observe that the model's behavior leads to positive outcomes.

Self-Efficacy

Bandura discusses how a variety of personal factors (aspects of personality) govern behavior. In recent years, the factor he has emphasized most is self-efficacy (Bandura, 1993, 1995, 2004). *Self-efficacy refers to one's belief about one's ability to perform behaviors that should lead to expected outcomes.* When self-efficacy is high, individuals feel confident that they can execute the responses necessary to earn reinforcers. When self-efficacy is low, individuals worry that the necessary responses may be beyond their abilities. Perceptions of self-efficacy are subjective and specific to certain kinds of tasks. For instance, you might feel extremely confident about your ability to handle difficult social situations but doubtful about your ability to handle academic challenges.

Perceptions of self-efficacy can influence which challenges people tackle and how well they perform. Studies have found that feelings of greater self-efficacy are associated with reduced procrastination (Steel, 2007); greater success in giving up smoking (Boudreaux et al., 1998); greater adherence to an exercise regimen (Rimal, 2001); more effective weight-loss efforts (Linde et al., 2006); better outcomes in substance abuse treatment (Bandura, 1999a); more success in coping with medical rehabilitation (Waldrop et al., 2001); reduced disability from problems with chronic pain (Hadjistavropoulos et al., 2007); greater persistence and effort in academic pursuits (Zimmerman, 1995); higher levels of academic performance (Chemers, Hu, & Garcia, 2001); reduced vulnerability to anxiety and depression in childhood (Muris, 2002); less jealousy in romantic relationships (Hu, Zhang, & Li, 2005); enhanced performance in athletic competition (Kane et al., 1996); greater receptiveness to technological training (Christoph, Schoenfeld, & Tansky, 1998); greater success in searching for a new job (Saks, 2006); higher work-related performance

Perceptions of self-efficacy can influence which challenges people pursue and how well they perform. For example, research has linked self-efficacy to job performance and success in adhering to an exercise regime.

(Stajkovic & Luthans, 1998); and reduced strain from occupational stress (Grau, Salanova, & Peiro, 2001), among many other things.

Mischel and the Person-Situation Controversy

Walter Mischel was born in Vienna, not far from Freud's home. His family immigrated to the United States in 1939, when he was 9. After earning his doctorate in psychology, he spent many years on the faculty at Stanford, as a colleague of Bandura's. He has since moved to Columbia University.

Like Bandura, Mischel (1973, 1984) is an advocate of social learning theory. Mischel's chief contribution to personality theory has been to focus attention on the extent to which situational factors govern behavior. According to social learning theory, people try to gauge the reinforcement contingencies and adjust their behavior to the circumstances. For example, if you believe that hard work in your job will pay off by leading to raises and promotions, you'll probably be diligent and industrious. But if you think that hard work in your job is unlikely to be rewarded, you may act lazy and irresponsible. Thus, social learning theory predicts that people will often behave differently in different situations.

Mischel (1968, 1973) reviewed decades of research and concluded that, indeed, people exhibit far less consistency across situations than had been widely assumed. For example, studies show that a person who is honest in one situation may be dishonest in another. That is, someone who wouldn't dream of being dishonest in a business deal might engage in wholesale cheating in filling out tax returns. Similarly, some people are quite shy in one situation and outgoing in another. In light of these realities,

Mischel maintains that behavior is characterized by more *situational specificity* than consistency.

Mischel's position has generated great controversy because it strikes at the heart of the concept of personality itself. As we discussed at the beginning of the chapter, the concept of personality is used to explain consistency in people's behavior over time and situations. If there isn't much consistency, there isn't much need for the concept of personality.

Mischel's views have generated many rebuttals that have defended the value of the personality concept. For instance, Epstein (1980, 1986) argued that the methods used in much of the research reviewed by Mischel led to an underestimate of cross-situational consistency. Critics also noted that it is unreasonable to expect complete cross-situational consistency, because specific traits are more easily expressed in some situations than others (Kenrick & Funder, 1991). For example, a person's fun-loving, humorous qualities aren't likely to be apparent at a funeral.

Thus, Mischel's provocative theories have sparked a robust debate about the relative importance of the *person* as opposed to the *situation* in determining behavior. This debate has led to a growing recognition that *both* the person and the situation are important determinants of behavior (Funder, 2001; Roberts & Pomerantz, 2004). As William Fleeson (2004) puts it, "The person-situation debate is coming to an end because both sides of the debate have turned out to
Walter Mischel

"It seems remarkable how each of us generally manages to reconcile his seemingly diverse behavior into one self-consistent whole."

be right" (p. 83). Fleeson reconciles the two opposing views by arguing that each prevails at a different level of analysis. When small chunks of behavior are examined on a moment-to-moment basis, situational factors dominate and most individuals' behavior tends to be highly variable. However, when larger chunks of typical behavior over time are examined, people tend to be reasonably consistent and personality traits prove to be more influential.

Evaluating Behavioral Perspectives

Behavioral theories are firmly rooted in extensive empirical research rather than clinical intuition. Skinner's ideas have shed light on how environmental consequences and conditioning mold people's characteristic behavior. Bandura's social cognitive theory has expanded the horizons of behaviorism and increased its relevance to the study of personality. Mischel deserves credit for increasing psychology's awareness of how situational factors shape behavior. Of course, each theoretical approach has its weaknesses and shortcomings, and the behavioral approach is no exception. Major lines of criticism include the following (Liebert & Liebert, 1998; Pervin & John, 2001):

1. *Dehumanizing nature of radical behaviorism.* Skinner and other radical behaviorists have been criticized heavily for denying the existence of free will and the importance of cognitive processes. The critics argue that the radical behaviorist viewpoint strips human behavior of its most uniquely human elements and that it therefore cannot provide an accurate model of human functioning.

2. *Dilution of the behavioral approach.* The behaviorists used to be criticized because they neglected cognitive processes, which clearly are important factors in human behavior. The rise of social cognitive theory blunted this criticism. However, social cognitive theory undermines the foundation on which behaviorism was built—the idea that psychologists should study only observable behavior. Thus, some critics complain that behavioral theories aren't very behavioral anymore.

3. *Fragmentation of personality.* Behaviorists have also been criticized for providing a fragmented view of personality. The behavioral approach carves personality up into stimulus-response associations. There are no unifying structural concepts (such as Freud's ego) that tie these pieces together. Humanistic theorists, whom we shall cover next, have been particularly vocal in criticizing this piecemeal analysis of personality.

REVIEW of Key Learning Goals

12.9 Skinner had little interest in unobservable cognitive processes and embraced a strong determinism. Skinner's followers view personality as a collection of response tendencies tied to specific stimulus situations. They assume that personality development is a lifelong process in which response tendencies are shaped and reshaped by learning, especially operant conditioning.

12.10 Social cognitive theory focuses on how cognitive factors such as expectancies regulate learned behavior. The Featured Study provided support for the assertion that people choose and shape their environments, consistent with Bandura's reciprocal determinism. High self-efficacy has been related to successful health regimens, academic success, and athletic performance, among many other things.

12.11 Mischel has questioned the degree to which people display cross-situational consistency in behavior. Mischel's arguments have increased psychologists' awareness of the situational determinants of behavior. According to Fleeson, situational factors dominate small chunks of behavior, whereas personality traits shape larger chunks of behavior.

12.12 Behavioral approaches to personality are based on rigorous research. They have provided ample insights into how environmental factors and learning mold personalities. This approach has been criticized for its fragmented analysis of personality, for radical behaviorism's dehumanizing view of human nature, and for the dilution of modern behavioral approaches.

Humanistic Perspectives

Key Learning Goals

12.13 Identify the impetus for, and assumptions of, humanism.

12.14 Articulate Rogers's views on self-concept, development, and defensive behavior.

12.15 Explain Maslow's hierarchy of needs, and summarize his findings on self-actualizing persons.

12.16 Evaluate the strengths and weaknesses of the humanistic approach to personality.

Humanistic theory emerged in the 1950s as something of a backlash against the behavioral and psychodynamic theories that we have just discussed (Cassel, 2000; DeCarvalho, 1991). The principal charge hurled at these two models was that they are dehumanizing. Freudian theory was criticized for its belief that behavior is dominated by primitive, animalistic drives. Behaviorism was criticized for its preoccupation with animal research and for its mechanistic, fragmented view of personality. Critics argued that both schools of thought are too deterministic and that both fail to recognize the unique qualities of human behavior.

Many of these critics blended into a loose alliance that came to be known as humanism, because of its exclusive focus on human behavior. *Humanism is a theoretical orientation that emphasizes the unique qualities of humans, especially their freedom and their potential for personal growth.* Humanistic psychologists don't believe that animal

research can reveal anything of any significance about the human condition. In contrast to most psychodynamic and behavioral theorists, humanistic theorists take an optimistic view of human nature. They assume that (1) people can rise above their primitive animal heritage and control their biological urges, and (2) people are largely conscious and rational beings who are not dominated by unconscious, irrational needs and conflicts.

Humanistic theorists also maintain that a person's subjective view of the world is more important than objective reality (Wong, 2006). According to this notion, if you think that you're homely or bright or sociable, this belief will influence your behavior more than the realities of how homely, bright, or sociable you actually are. Therefore, the humanists embrace the *phenomenological approach,* **which assumes that one has to appreciate individuals' personal, subjective experiences to truly understand their behavior.** As Carl Rogers (1951) put it, "The best vantage point for understanding behavior is from the internal frame of reference of the individual himself" (p. 494). Let's look at Rogers's ideas.

Rogers's Person-Centered Theory   10c

Carl Rogers (1951, 1961, 1980) was one of the founders of the human potential movement. This movement emphasizes self-realization through sensitivity training, encounter groups, and other exercises intended to foster personal growth. Rogers grew up in a religious, upper-middle-class home in the suburbs of Chicago. He was a bright student, but he had to rebel against his parents' wishes in order to pursue his graduate study in psychology. While he was working at the University of Chicago in the 1940s, Rogers devised a major new approach to psychotherapy. Like Freud, Rogers based his personality theory on his extensive therapeutic interactions with many clients. Because of its emphasis on a person's subjective point of view, Rogers's approach is called a *person-centered theory.*

The Self   10c

Rogers viewed personality structure in terms of just one construct. He called this construct the *self,* although it's more widely known today as the *self-concept.* **A *self-concept* is a collection of beliefs about one's own nature, unique qualities, and typical behavior.** Your self-concept is your own mental picture of yourself. It's a collection of self-perceptions. For example, a self-concept might include beliefs such as "I'm easygoing" or "I'm sly

and crafty" or "I'm pretty" or "I'm hardworking." According to Rogers, individuals are aware of their self-concept. It's not buried in their unconscious.

Rogers stressed the subjective nature of the self-concept. Your self-concept may not be entirely consistent with your experiences. Most people tend to distort their experiences to some extent to promote a relatively favorable self-concept. For example, you may believe that you're quite bright, but your grade transcript might suggest otherwise. Rogers called the gap between self-concept and reality "incongruence." *Incongruence* **is the degree of disparity between one's self-concept and one's actual experience.** In contrast, if a person's self-concept is reasonably accurate, it's said to be *congruent* with reality (see Figure 12.9). Everyone experiences *some* incongruence. The crucial issue is how much. As we'll see, Rogers maintained that too much incongruence undermines one's psychological well-being.

Development of the Self   10c

In terms of personality development, Rogers was concerned with how childhood experiences promote congruence or incongruence between one's self-concept and one's experience. According to Rogers, people have a strong need for affection, love, and acceptance from others. Early in life, parents provide most of this affection. Rogers maintained that some parents make their affection *conditional.* That is, it depends on the child's behaving well and living up to expectations. When parental love seems conditional, children often block out of their self-concept those experiences that make them feel unworthy of love. They do so because they're worried about parental acceptance, which appears precarious. At the other end of the spectrum, some parents make their affection *unconditional.* Their children

Carl Rogers

"I have little sympathy with the rather prevalent concept that man is basically irrational, and that his impulses, if not controlled, will lead to destruction of others and self. Man's behavior is exquisitely rational, moving with subtle and ordered complexity toward the goals his organism is endeavoring to achieve."

Congruence
Self-concept meshes well with actual experience (some incongruence is probably unavoidable)

Incongruence
Self-concept does not mesh well with actual experience

Figure 12.9
Rogers's view of personality structure. In Rogers's model, the self-concept is the only important structural construct. However, Rogers acknowledged that one's self-concept may not be consistent with the realities of one's actual experience—a condition called incongruence.

is a "self-centered, snotty brat." How might she react in order to protect her self-concept? She might ignore or block out those occasions when she behaves selfishly. She might attribute her girlfriends' negative comments to their jealousy of her good looks. Perhaps she would blame her boyfriends' negative remarks on their disappointment because she won't get more serious with them. As you can see, people will sometimes go to great lengths to defend their self-concept.

Maslow's Theory of Self-Actualization   10c

Abraham Maslow, who grew up in Brooklyn, described his childhood as "unhappy, lonely, [and] isolated." To follow through on his interest in psychology, he had to resist parental pressures to go into law. Maslow spent much of his career at Brandeis University, where he created an influential theory of motivation and provided crucial leadership for the fledgling humanistic movement. Like Rogers, Maslow (1968, 1970) argued that psychology should take an optimistic view of human nature instead of dwelling on the causes of disorders. "To oversimplify the matter somewhat," he said, "it's as if Freud supplied to us the sick half of psychology and we must now fill it out with the healthy half" (1968, p. 5). Maslow's key contributions were his analysis of how motives are organized hierarchically and his description of the healthy personality.

have less need to block out unworthy experiences because they've been assured that they're worthy of affection, no matter what they do.

Hence, Rogers believed that unconditional love from parents fosters congruence and that conditional love fosters incongruence. He further theorized that if individuals grow up believing that affection from others is highly conditional, they will go on to distort more and more of their experiences in order to feel worthy of acceptance from a wider and wider array of people (see **Figure 12.10**).

Anxiety and Defense   10c

According to Rogers, experiences that threaten people's personal views of themselves are the principal cause of anxiety. The more inaccurate your self-concept, the more likely you are to have experiences that clash with your self-perceptions. Thus, people with highly incongruent self-concepts are especially likely to be plagued by recurrent anxiety (see **Figure 12.10**).

To ward off this anxiety, individuals often behave defensively in an effort to reinterpret their experience so that it appears consistent with their self-concept. Thus, they ignore, deny, and twist reality to protect and perpetuate their self-concept. Consider a young woman who, like most people, considers herself a "nice person." Let's suppose that in reality she is rather conceited and selfish. She gets feedback from both boyfriends and girlfriends that she

Hierarchy of Needs   10c

Maslow proposed that human motives are organized into a *hierarchy of needs*—a systematic arrangement of needs, according to priority, in which basic needs must be met before less basic needs are aroused. This hierarchical arrangement is usually portrayed as a pyramid (see **Figure 12.11**). The needs toward the bottom of the pyramid, such as physiological or security needs, are the most basic. Higher levels in the pyramid consist of progressively less basic needs. When a person manages to satisfy a

Figure 12.10
Rogers's view of personality development and dynamics. Rogers's theory of development posits that conditional love leads to a need to distort experiences, which fosters an incongruent self-concept. Incongruence makes one prone to recurrent anxiety, which triggers defensive behavior, which fuels more incongruence.

Progression
if lower needs
are satisfied

Need for self-actualization:
Realization of potential

Aesthetic needs:
Order and beauty

Cognitive needs:
Knowledge and understanding

Esteem needs:
Achievement and gaining of recognition

Belongingness and love needs:
Affiliation and acceptance

Safety and security needs:
Long-term survival and stability

Physiological needs:
Hunger, thirst, and so forth

Regression
if lower needs
are not being
satisfied

Figure 12.11
Maslow's hierarchy of needs. According to Maslow, human needs are arranged in a hierarchy, and people must satisfy their basic needs before they can satisfy higher needs. In the diagram, higher levels in the pyramid represent progressively less basic needs. Individuals progress upward in the hierarchy when lower needs are satisfied reasonably well, but they may regress back to lower levels if basic needs are no longer satisfied.

level of needs reasonably well (complete satisfaction is not necessary), *this satisfaction activates needs at the next level.*

Like Rogers, Maslow argued that humans have an innate drive toward personal growth—that is, evolution toward a higher state of being. Thus, he described the needs in the uppermost reaches of his hierarchy as *growth needs.* These include the needs for knowledge and aesthetic beauty. Foremost among them is the **need for self-actualization, which is the need to fulfill one's potential;** it is the highest need in Maslow's motivational hierarchy. Maslow summarized this concept with a simple statement: "What a man *can* be, he *must* be." According to Maslow, people will be frustrated if they are unable to fully utilize their talents or pursue their true interests. For example, if you have great musical talent but must work as an accountant, or if you have scholarly interests but must work as a sales clerk, your need for self-actualization will be thwarted.

The Healthy Personality   10c

Because of his interest in self-actualization, Maslow set out to discover the nature of the healthy personality. He tried to identify people of exceptional mental health so that he could investigate their characteristics. In one case, he used psychological tests and interviews to sort out the healthiest 1% of a sizable population of college students. He also studied admired historical figures (such as Thomas Jefferson and William James) and personal acquaintances characterized by superior adjustment. Over a period of years, he accumulated his case histories

and gradually sketched, in broad strokes, a picture of ideal psychological health.

According to Maslow, *self-actualizing persons are people with exceptionally healthy personalities, marked by continued personal growth.* Maslow identified various traits characteristic of self-actualizing people. Many of these traits are listed in **Figure 12.12**. In brief, Maslow found that self-actualizers are accurately tuned in to reality and that they're at peace with themselves. He found that they're open and spontaneous and that they retain a fresh appreciation of the world around them. Socially, they're sensitive to others' needs and enjoy

Abraham Maslow

"It is as if Freud supplied to us the sick half of psychology and we must now fill it out with the healthy half."

Characteristics of self-actualizing people

- Clear, efficient perception of reality and comfortable relations with it
- Spontaneity, simplicity, and naturalness
- Problem centering (having something outside themselves they "must" do as a mission)
- Detachment and need for privacy
- Autonomy, independence of culture and environment
- Continued freshness of appreciation

- Mystical and peak experiences
- Feelings of kinship and identification with the human race
- Strong friendships, but limited in number
- Democratic character structure
- Ethical discrimination between good and evil
- Philosophical, unhostile sense of humor
- Balance between polarities in personality

Figure 12.12
Maslow's view of the healthy personality. Humanistic theorists emphasize psychological health instead of maladjustment. Maslow's description of characteristics of self-actualizing people evokes a picture of the healthy personality.

PEANUTS reprinted by permission of United Feature Syndicate, Inc.
rewarding interpersonal relations. However, they're not dependent on others for approval or uncomfortable with solitude. They thrive on their work, and they enjoy their sense of humor. Maslow also noted that they have "peak experiences" (profound emotional highs) more often than others. Finally, he found that they strike a nice balance between many polarities in personality. For instance, they can be both childlike and mature, both rational and intuitive, both conforming and rebellious.

Evaluating Humanistic Perspectives

The humanists added a refreshing new perspective to the study of personality. Their argument that a person's subjective views may be more important than objective reality has proven compelling. As we noted earlier, even behavioral theorists have begun to take into account subjective personal factors such as beliefs and expectations. The humanistic approach also deserves some of the credit for making the self-concept an important construct in psychol-

ogy. Finally, one could argue that the humanists' optimistic, growth- and health-oriented approach laid the foundation for the emergence of the positive psychology movement that is increasingly influential in contemporary psychology (Sheldon & Kasser, 2001; Taylor, 2001).

Of course, there's a negative side to the balance sheet as well. Critics have identified some weaknesses in the humanistic approach to personality, including the following (Burger, 2008; Wong, 2006):

1. *Poor testability.* Like psychodynamic theorists, the humanists have been criticized for generating hypotheses that are difficult to put to a scientific test. Humanistic concepts such as personal growth and self-actualization are difficult to define and measure.

2. *Unrealistic view of human nature.* Critics also charge that the humanists have been unrealistic in their assumptions about human nature and their descriptions of the healthy personality. For instance, Maslow's self-actualizing people sound nearly *perfect.* In reality, Maslow had a hard time finding such

concept check 12.2

Recognizing Key Concepts in Personality Theories

Check your understanding of psychodynamic, behavioral, and humanistic personality theories by identifying key concepts from these theories in the scenarios below. The answers can be found in Appendix A.

1. Thirteen-year-old Sarah watches a TV show in which the leading female character manipulates her boyfriend by acting helpless and purposely losing a tennis match against him. The female lead repeatedly expresses her slogan, "Never let them [men] know you can take care of yourself." Sarah becomes more passive and less competitive around boys her own age.

   Concept: _____

2. Yolanda has a secure, enjoyable, reasonably well-paid job as a tenured English professor at a state university. Her friends are dumbfounded when she announces that she's going to resign and give it all up to try writing a novel. She tries to explain, "I need a new challenge, a new mountain to climb. I've had this lid on my writing talents for years, and I've got to break free. It's something I have to try. I won't be happy until I do."

   Concept: _____

3. Vladimir, who is 4, seems to be emotionally distant from and inattentive to his father. He complains whenever he's left with his dad. In contrast, he often cuddles up in bed with his mother and tries very hard to please her by behaving properly.

   Concept: _____

people. When he searched among the living, the results were so disappointing that he turned to the study of historical figures. Thus, humanistic portraits of psychological health are perhaps a bit too optimistic.

   3. *Inadequate evidence.* For the most part, humanistic psychologists haven't been particularly research oriented. Although Rogers and Maslow both conducted and encouraged empirical research, many of their followers have been scornful of efforts to quantify human experience to test hypotheses. Much more research is needed to catch up with the theorizing in the humanistic camp. This is precisely the opposite of the situation that we'll encounter in the next section, which examines biological approaches to personality.

REVIEW of Key Learning Goals

12.13 Humanism emerged as a backlash against psychodynamic and behavioral theories, which were viewed as overly deterministic and dehumanizing. Humanistic theories are phenomenological and take an optimistic view of people's conscious, rational ability to chart their own courses of action.

12.14 Rogers focused on the self-concept as the critical aspect of personality. Incongruence is the degree of disparity between one's self-concept and actual experience. Rogers maintained that unconditional love fosters congruence, whereas conditional love fosters incongruence. Incongruence makes one vulnerable to recurrent anxiety, which tends to trigger defensive behavior that protects one's inaccurate self-concept.

12.15 Maslow theorized that needs are organized hierarchically and that psychological health depends on fulfilling one's need for self-actualization, which is the need to realize one's human potential. His work led to the description of self-actualizing persons as idealized examples of psychological health.

12.16 Humanistic theories deserve credit for highlighting the importance of subjective views of oneself and for confronting the question of what makes for a healthy personality. Humanistic theories lack a firm base of research, are difficult to put to an empirical test, and may be overly optimistic about human nature.

Biological Perspectives

Like many identical twins reared apart, Jim Lewis and Jim Springer found they had been leading eerily similar lives. Separated four weeks after birth in 1940, the Jim twins grew up 45 miles apart in Ohio and were reunited in 1979. Eventually, they discovered that both drove the same model blue Chevrolet, chain-smoked Salems, chewed their fingernails, and owned dogs named Toy. Each had spent a good deal of time vacationing at the same three-block strip of beach in Florida. More important, when tested for such personality traits as flexibility, self-control, and sociability, the twins responded almost exactly alike. (Leo, 1987, p. 63)

So began a *Time* magazine summary of a major twin study conducted at the University of Minnesota Center for Twin and Adoption Research. Since 1979 the investigators at this center have been studying the personality resemblance of identical twins reared apart. Not all the twin pairs have been as similar as Jim Lewis and Jim Springer, but many of the parallels have been uncanny (Lykken et al., 1992). Identical twins Oskar Stohr and Jack Yufe were separated soon after birth. Oskar was sent to a Nazirun school in Czechoslovakia while Jack was raised in a Jewish home on a Caribbean island. When they were reunited for the first time during middle age, they showed up wearing similar mustaches, hair-cuts, shirts, and wire-rimmed glasses! A pair of previously separated female twins both arrived at the Minneapolis airport wearing seven rings on their fingers. One had a son named Richard Andrew and the other had a son named Andrew Richard!

Could personality be largely inherited? These anecdotal reports of striking resemblances between identical twins reared apart certainly raise this possibility. In this section we'll discuss Hans Eysenck's theory, which emphasizes the influence of heredity, look at recent behavioral genetics research on the heritability of personality, and outline the evolutionary perspective on personality.

Eysenck's Theory   10d

Hans Eysenck was born in Germany but fled to London during the era of Nazi rule. He went on to become one of Britain's most prominent psychologists. Eysenck (1967, 1982, 1990a) viewed personality structure as a hierarchy of traits, in which many superficial traits are derived from a smaller number of more basic traits, which are derived from a handful of fundamental higher-order traits, as shown in **Figure 12.13** on the next page. His studies suggested that all aspects of personality emerge from just three higher-order traits: extraversion, neuroticism,

Key Learning Goals

12.17 Outline Eysenck's views of personality structure and development.

12.18 Summarize the findings of behavioral genetics research on personality.

12.19 Articulate Buss's and Nettle's evolutionary explanations for why the Big Five traits are important.

12.20 Assess the strengths and weaknesses of the biological approach to personality.

Is personality largely inherited? The story of these identical twins would certainly suggest so. Although they were reared apart from 4 weeks after their birth, Jim Lewis (left) and Jim Springer (right) exhibit remarkable correspondence in personality. Some of the similarities in their lives—such as the benches built around trees in their yards—seem uncanny.

Hans Eysenck

"Personality is determined to a large extent by a person's genes."

and psychoticism, which involves being egocentric, impulsive, cold, and antisocial.

According to Eysenck, "Personality is determined to a large extent by a person's genes" (1967, p. 20). How is heredity linked to personality in Eysenck's model? In part, through conditioning concepts borrowed from behavioral theory. Eysenck theorized that some people can be conditioned more readily than others because of differences in their physiological functioning. These variations in "conditionability" are assumed to influence the personality traits that people acquire through conditioning processes.

Eysenck has shown a special interest in explaining variations in *extraversion-introversion*. He has proposed that introverts tend to have higher levels of physiological arousal, or perhaps higher "arousability," which make them more easily conditioned than extraverts. According to Eysenck, people who

condition easily acquire more conditioned inhibitions than others. These inhibitions make them more bashful, tentative, and uneasy in social situations. This social discomfort leads them to turn inward. Hence, they become introverted.

Behavioral Genetics and Personality

10d

Recent research in behavioral genetics has provided impressive support for the idea that many personality traits are largely inherited (Livesley, Jang, Vernon, 2003; Rowe & van den Oord, 2005). For instance, **Figure 12.14** shows the mean correlations observed for identical and fraternal twins in studies of the Big Five personality traits. Higher correlations are indicative of greater similarity on a trait. On all five traits, identical twins have been found to be much more similar than fraternal twins (Plomin et al., 2008). Based on these and many other findings, theorists conclude that genetic factors exert considerable influence over personality (see Chapter 3 for an explanation of the logic of twin studies).

Some skeptics wonder whether identical twins might exhibit more trait similarity than fraternal twins because they're treated more alike. In other words, they wonder whether environmental factors (rather than heredity) could be responsible for identical twins' greater personality resemblance. This nagging question can be answered only by studying identical twins reared apart, which is why the twin study at the University of Minnesota has been so important. The Minnesota study (Tellegen et al., 1988) was the first to administer the same personality test to identical and fraternal twins reared apart, as well as together. Most of the twins reared apart were separated quite early in life (median age of 2.5 months) and remained separated for a long time (median period of almost 34 years).

The results revealed that identical twins reared apart were substantially more similar in personality

Figure 12.13

Eysenck's model of personality structure.

Eysenck described personality structure as a hierarchy of traits. In this scheme, a few higher-order traits, such as extraversion, determine a number of lower-order traits, which determine a person's habitual responses.

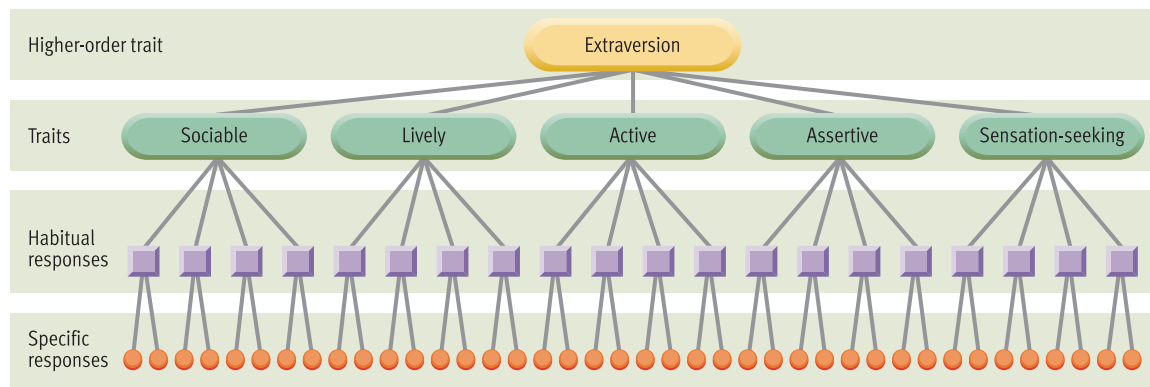

Figure 12.14

Twin studies of personality. Loehlin (1992) has summarized the results of twin studies that have examined the Big Five personality traits. The N under each trait indicates the number of twin studies that have examined that trait. The chart plots the average correlations obtained for identical and fraternal twins in these studies. As you can see, identical twins have shown greater resemblance in personality than fraternal twins have, suggesting that personality is partly inherited. (Based on data from Loehlin, 1992)

than fraternal twins reared together. The *heritability estimates* (see Chapter 9) for the traits examined ranged from 40% to 58%. The investigators concluded that their results support the hypothesis that genetic blueprints shape the contours of personality.

Research on the heritability of personality has inadvertently turned up an interesting discovery: *shared family environment* appears to have remarkably little impact on personality. This unexpected finding has been observed quite consistently in behavioral genetics research (Beer, Arnold, & Loehlin, 1998; Rowe & van den Oord, 2005). It is surprising in that social scientists have long assumed that the family environment shared by children growing up together led to some personality resemblance among them. *These findings have led some theorists to conclude that parents don't matter—that they wield very little influence over how their children develop* (Cohen, 1999; Harris, 1998; Rowe, 1994).

Critics of this conclusion have argued that the methods used in behavioral genetics studies have probably underestimated the impact of shared environment on personality (Collins et al., 2000; Stoolmiller, 1999). They also note that shared experiences—such as being raised with authoritarian discipline—may often have different effects on two siblings, which obscures the impact of environment

but is not the same result as having no effect (Turkheimer & Waldron, 2000). And the critics argue that decades of research in developmental psychology have clearly demonstrated that parents have significant influence on their children (Maccoby, 2000). Thus, the assertion that "parents don't matter" seems premature and overstated.

The Evolutionary Approach to Personality

In the realm of biological perspectives on personality, another recent development has been the emergence of evolutionary theory. Evolutionary theorists assert that personality has a biological basis because natural selection has favored certain traits over the course of human history (Figueredo et al., 2005). Thus, evolutionary analyses focus on how various personality traits—and the ability to recognize these traits in others—may have contributed to reproductive fitness in ancestral human populations.

For example, David Buss (1991, 1995, 1997) has argued that the Big Five personality traits stand out as important dimensions of personality because those traits have had significant adaptive implications. Buss points out that humans historically have depended heavily on groups, which afford protection

David Buss

"In sum, the five factors of personality, in this account, represent important dimensions of the social terrain that humans were selected to attend to and act upon."

Courtesy of David M. Buss

from predators or enemies, opportunities for sharing food, and a diverse array of other benefits. In the context of these group interactions, people have had to make difficult but crucial judgments about the characteristics of others, asking such questions as: Who will make a good member of my coalition? Who can I depend on when in need? Who will share their resources? Thus, Buss (1995) argues, "those individuals able to accurately discern and act upon these individual differences likely enjoyed a considerable reproductive advantage" (p. 22).

According to Buss, the Big Five traits emerge as fundamental dimensions of personality because humans have evolved special sensitivity to variations in the ability to bond with others (extraversion), the willingness to cooperate and collaborate (agreeableness), the tendency to be reliable and ethical (conscientiousness), the capacity to be an innovative problem solver (openness to experience), and the ability to handle stress (low neuroticism). In a nutshell, Buss argues that the Big Five reflect the most salient features of others' adaptive behavior over the course of evolutionary history.

Daniel Nettle (2006) takes this line of thinking one step further, asserting that the traits themselves (as opposed to the ability to recognize them in others) are products of evolution that were adaptive in ancestral environments. For example, he discusses how extraversion could have promoted mating success, how neuroticism could have fueled competitiveness and avoidance of dangers, how agreeableness could have fostered the effective building of coalitions, and so forth. Nettle also discusses how

each of the Big Five traits may have had adaptive costs (extraversion, for example, is associated with risky behavior) as well as benefits. Thus, he argues that evolutionary analyses of personality need to weigh the *trade-offs* between the adaptive advantages and disadvantages of the Big Five traits.

Evaluating Biological Perspectives

Researchers have compiled convincing evidence that biological factors exert considerable influence over personality. Nonetheless, we must take note of some weaknesses in biological approaches to personality:

1. David Funder (2001) has observed that behavioral genetics researchers exhibit something of an "obsession with establishing the exact magnitude of heritability coefficients" (p. 207). As we discussed in Chapter 9, heritability ratios are ballpark estimates that will vary depending on sampling procedures and other considerations (Sternberg, Grigorenko, & Kidd, 2005). There is no one magic number awaiting discovery, so the inordinate focus on heritability does seem ill-advised.

2. At present there's no comprehensive biological theory of personality. Eysenck's model doesn't provide a systematic overview of how biological factors govern personality structure and development (and was never intended to). In regard to personality, evolutionary theory is even more limited in scope than Eysenck's theory. Additional theoretical work is needed to catch up with recent empirical findings on the biological basis for personality.

A Contemporary Empirical Approach: Terror Management Theory

So far, our coverage has been largely devoted to grand, panoramic theories of personality. In this section we'll examine a new approach to understanding personality functioning that has a narrower focus than the classic theories of personality. *Terror management theory* emerged as an influential perspective in the 1990s. Although the theory borrows from Freudian and evolutionary formulations, it provides its own unique analysis of the human condition. Developed by Sheldon Solomon, Jeff Greenberg, and Tom Pyszczynski (1991, 2004b), this fresh perspective is currently generating a huge volume of research.

Essentials of Terror Management Theory

One of the chief goals of terror management theory is to explain why people need self-esteem (Solomon, Greenberg, & Pyszczynski, 1991). The theory begins by noting that humans have evolved complex cognitive abilities that permit self-awareness and contemplation of the future. These cognitive capacities make humans keenly aware of the inevitability of death—they appreciate that life can be snuffed out unpredictably at any time. Humans' awareness of the inevitability of death creates the potential for experiencing anxiety, alarm, and terror when individuals think about their mortality (see **Figure 12.15**).

How do people deal with this potential for terror? According to terror management theory, "What saves us is culture. Cultures provide ways to view the world—worldviews—that 'solve' the existential crisis engendered by the awareness of death" (Pyszczynski, Solomon, & Greenberg, 2003, p. 16). Cultural world-

views diminish anxiety by providing answers to such universal questions as: Why am I here? What is the meaning of life? Cultures create stories, traditions, and institutions that give their members a sense of being part of an enduring legacy through their contributions to their families, tribes, schools, churches, professions, and so forth. Thus, faith in a cultural worldview can give people a sense of order, meaning, and context that can soothe humans' fear of death.

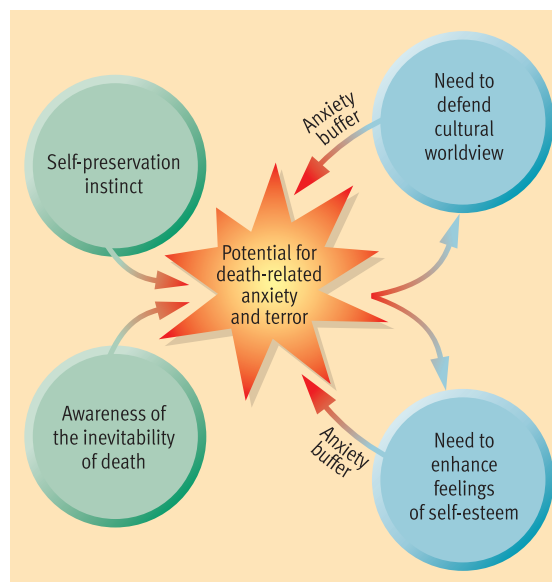
Where does self-esteem fit into the picture? Self-esteem is viewed as a sense of personal worth that depends on one's confidence in the validity of one's cultural worldview and the belief that one is living up to the standards prescribed by that worldview. "It is the feeling that one is a valuable contributor to a meaningful universe" (Pyszczynski et al., 2004,


Figure 12.15
Overview of terror management theory. This graphic maps out the relations among the key concepts proposed by terror management theory. The theory asserts that humans' unique awareness of the inevitability of death fosters a need to defend one's cultural worldview and one's self-esteem, which serve to protect one from mortality-related anxiety.

p. 437). Hence, self-esteem buffers people from the profound anxiety associated with the awareness that we are transient animals destined to die. In other words, self-esteem serves a *terror management* function (refer to **Figure 12.15**).

The notion that self-esteem functions as an *anxiety buffer* has been supported by numerous studies (Pyszczynski et al., 2004). In many of these experiments, researchers have manipulated what they call *mortality salience* by asking subjects to briefly think about their own death. Consistent with the anxiety buffer hypothesis, reminding people of their mortality leads subjects to engage in a variety of behaviors that are likely to bolster their self-esteem, thus reducing anxiety.

Applications of Terror Management Theory

Increasing mortality salience also leads people to work harder at defending their cultural worldview (Arndt, Cook, & Routledge, 2004). For instance, after briefly pondering their mortality, research participants (1) hand out harsher penalties to moral transgressors, (2) respond more negatively to people who criticize their culture, and (3) show more respect for cultural icons, such as a flag (Greenberg et al., 1990; Rosenblatt et al., 1989). This need to defend one's cultural worldview may even fuel prejudice. Reminding subjects of their mortality leads to (1) more negative evaluations of people from different religious or ethnic backgrounds, and (2) more stereotypic thinking about minority group members (McGregor et al., 1998; Schimel et al., 1999).

Terror management theory asserts that much of people's behavior is motivated by the overlap-

According to terror management theory, events that remind people of their mortality motivate them to defend their cultural worldview. One manifestation of this process is an increased interest in, and respect for, cultural icons, such as flags.

© Gilles Peress/Magnum Photos

ping needs to defend their cultural worldview and preserve their self-esteem. This perspective yields novel hypotheses regarding many phenomena. For instance, Solomon, Greenberg, and Pyszczynski (2004a) explain excessive materialism in terms of the anxiety-buffering function of self-esteem. Specifically, they argue that "conspicuous possession and consumption are thinly veiled efforts to assert that one is special and therefore more than just an animal fated to die and decay" (p. 134). One recent study even applied terror management theory to the political process. Cohen et al. (2004) found that mortality salience increased participants' preference for "charismatic" candidates who articulate a grand vision that makes people feel like they are part of an important movement of lasting significance.

In another thought-provoking analysis, Goldenberg (2005) argues that bodily concerns remind people of their animal nature and hence their ultimate mortality. Based on this analysis, Goldenberg and colleagues have predicted and found that mortality salience can increase individuals' ambivalence about the physical aspects of sexuality and lead to the suppression of some sexual urges (Goldenberg et al., 2002; Landau, Goldenberg et al., 2006). Mortality salience can also inhibit health-protective behaviors, such as breast self-exams by women, when these behaviors highlight the frailty of the human body.

As you can see, although terror management theory is narrower in scope than psychoanalytic, behavioral, and humanistic theories, it has wide-ranging implications. In particular, given its focus on death anxiety, it has much to say about people's reactions to the contemporary threat of terrorism. Pyszczynski, Solomon, and Greenberg (2003) point out that terrorist attacks are intended to produce a powerful, nationwide manipulation of mortality salience. When mortality salience is elevated, terror management theory predicts that people will embrace their cultural worldviews even more strongly than before. Consistent with this prediction, in the months following the September 11 terrorist attacks on New York and Washington, D.C., expressions of patriotism and religious faith increased dramatically. Research on terror management processes has also shown that when death anxiety is heightened, people become less tolerant of opposing views and more prejudiced against those who are different. Consistent with this analysis, in the aftermath of September 11, individuals who questioned government policies met more hostility than usual. The theory also predicts that reminders of mortality increase the tendency to admire those who uphold cultural standards. More than ever, people need heroes who personify cultural values. This need was

apparent following September 11 in the way the media made firefighters into larger-than-life heroes.

At first glance, a theory that explains everything from prejudice to compulsive shopping in terms of death anxiety may seem highly implausible. After all, most people do not appear to walk around all day obsessing about the possibility of their death. The architects of terror management theory are well aware of this reality. They explain that the defensive reactions uncovered in their research generally occur when death anxiety surfaces on the fringes of conscious awareness and that these reactions are automatic and subconscious (Pyszczynski, Greenberg, & Solomon, 1999). They also assert that people experience far more reminders of their mortality than most of us appreciate. They point out that people may be reminded of their mortality by a variety of everyday events, such as driving by a cemetery or funeral home, reading about an auto accident, visiting a doctor's office, hearing about a celebrity's heart attack, learning about alarming medical research, and so forth. Thus, the processes discussed by terror management theory may be more commonplace that one might guess.

REVIEW of Key Learning Goals

12.21 Terror management theory proposes that self-esteem and faith in a cultural worldview shield people from the profound anxiety associated with their mortality. Consistent with this analysis, increasing mortality salience leads people to make efforts to bolster their self-esteem and defend their worldviews.

12.22 Manipulations of mortality salience lead to harsh treatment for moral transgressions, elevated respect for cultural icons, and increased prejudice. Terror management processes can shed light on conspicuous consumption, sexual discomfort, and reactions to terrorism.

Culture and Personality

Are there connections between culture and personality? The investigation of this question dates back to the 1940s and 1950s, when researchers set out to describe various cultures' *modal personality* (Kardiner & Linton, 1945) or *national character* (Kluckhohn & Murray, 1948). These investigations sought to describe the *prototype* or *typical* personality in various cultures. For example, Ruth Benedict (1934) concluded that American Pueblo Indians were sober, orderly, conventional, and cooperative. Largely guided by Freud's psychoanalytic theory, this line of research generated interest for a couple decades, but ultimately met with little success (Bock, 2000; LeVine, 2001). Part of the problem may have been the rather culture-bound, Eurocentric nature of Freudian theory, but the crux of the problem was that it was unrealistic to expect to find a single, dominant personality profile in each culture. As we have seen repeatedly, given the realities of multifactorial causation, behavior is never that simple.

Studies of the links between culture and personality dwindled after the disappointments of the 1940s and 1950s. However, in recent years psychology's new interest in cultural factors has led to a renaissance of culture-personality research. This research has sought to determine whether Western personality constructs are relevant to other cultures and whether cultural differences can be seen in the prevalence of specific personality traits. As with cross-cultural research in other areas of psychology, these studies have found evidence of both continuity and variability across cultures.

For the most part, continuity has been apparent in cross-cultural comparisons of the *trait structure* of personality. When English language personality scales have been translated and administered in other cultures, the predicted dimensions of personality have emerged from the factor analyses (Paunonen & Ashton, 1998). For example, when scales that tap the Big Five personality traits have been administered and subjected to factor analysis in other cultures, the usual five traits have typically emerged (Katigbak et al., 2002; McCrae et al., 2005). Thus, research tentatively suggests that the basic dimensions of personality trait structure may be universal.

On the other hand, some cross-cultural variability is seen when researchers compare the average trait scores of samples from various cultural groups. For example, in a study comparing 51 cultures, McCrae et al. (2005) found that Brazilians scored relatively high in neuroticism, Australians in extraversion, Germans in openness to experience, Czechs in agreeableness, and Malaysians in conscientiousness, to give but a handful of examples. These findings should be viewed as preliminary, since more data are needed from larger and more carefully selected samples. Nonetheless, the findings suggest that there may be genuine cultural differences on some personality traits. That said, the cultural disparities in average trait scores that were observed were pretty modest in size.

Key Learning Goals

12.23 Clarify how researchers have found both cross-cultural similarities and disparities in personality.

12.24 Describe research on the accuracy of perceptions of national character.

12.25 Explain Markus and Kitayama's research on cultural variations in conceptions of self.

"Most of what psychologists currently know about human nature is based on one particular view—the so-called Western view of the individual as an independent, self-contained, autonomous entity."

Culture can shape personality. Children in Asian cultures, for example, grow up with a value system that allows them to view themselves as interconnected parts of larger social units. Hence, they tend to avoid positioning themselves so that they stand out from others.

The availability of the data from the McCrae et al. (2005) study allowed Terracciano et al. (2005) to revisit the concept of *national character.* Terracciano and his colleagues asked subjects from many cultures to describe the *typical* member of *their* culture on rating forms guided by the five-factor model. Generally, subjects displayed substantial agreement on these ratings of what was typical for their culture. The averaged ratings, which served as the measures of each culture's national character, were then correlated with the actual mean trait scores for various cultures compiled in the McCrae et al. (2005) study. The results were definitive—the vast majority of the correlations were extremely low and often even negative. In other words, there was little or no relationship between perceptions of national character and actual trait scores for various cultures (see **Figure 12.16**). People's beliefs about national character, which often fuel cultural prejudices, turned out to be profoundly inaccurate stereotypes (McCrae & Terracciano, 2006).

Perhaps the most interesting and influential work on culture and personality has been that of Hazel Markus and Shinobu Kitayama (1991, 1994, 2003) comparing American and Asian conceptions of the self. According to Markus and Kitayama, American parents teach their children to be self-reliant, to feel good about themselves, and to view themselves as special individuals. Children are encouraged to excel in competitive endeavors and to strive to stand out from the crowd. They are told that "the squeaky wheel gets the grease" and that "you have to stand up for yourself." Thus, Markus and Kitayama argue that *American culture fosters an independent view of the self.* American youngsters learn to define themselves in terms of their personal attributes, abilities, accom-
Figure 12.16

An example of inaccurate perceptions of national character. Terracciano et al. (2005) found that perceptions of national character (the prototype or typical personality for a particular culture) are largely inaccurate. The data shown here for one culture—Canadians—illustrates this inaccuracy. Mean scores on the Big Five traits for a sample of real individuals from Canada are graphed here in red. Averaged perceptions of national character for Canadians are graphed here in blue. The discrepancy between perception and reality is obvious. Terracciano and colleagues found similar disparities between views of national character and actual trait scores for a majority of the cultures they studied. (Adapted from McCrae & Terracciano, 2006)

plishments, and possessions. Their unique strengths and achievements become the basis for their sense of self-worth. Hence, they are prone to emphasize their uniqueness.

Most of us take this mentality for granted. Indeed, Markus and Kitayama maintain that "most of what psychologists currently know about human nature is based on one particular view—the so-called Western view of the individual as an independent, self-contained, autonomous entity" (1991, p. 224). However, they marshal convincing evidence that this view is *not* universal. They argue that in Asian cultures such as Japan and China, socialization practices foster a more *interdependent view of the self,* which emphasizes the fundamental connectedness of people to each other (see **Figure 12.17**). In these cultures, parents teach their children that they can rely on family and friends, that they should be modest about their personal accomplishments so they don't diminish others' achievements, and that they should view themselves as part of a larger social matrix. Children are encouraged to fit in with

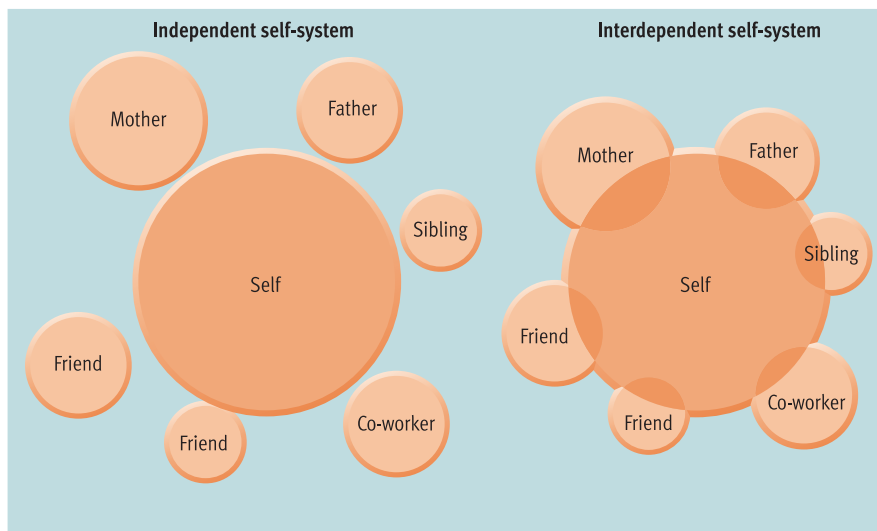

Figure 12.17

Culture and conceptions of self. According to Markus and Kitayama (1991), Western cultures foster an independent view of the self as a unique individual who is separate from others, as diagrammed on the left. In contrast, Asian cultures encourage an interdependent view of the self as part of an interconnected social matrix, as diagrammed on the right. The interdependent view leads people to define themselves in terms of their social relationships (for instance, as someone's daughter, employee, colleague, or neighbor).

SOURCE: Adapted from Markus, H. R., & Kitayama, S. (1991). Culture and the self: Implications for cognition, emotion, and motivation. *Psychological Review, 98*, 224–253. Copyright © 1991 by the American Psychological Association. Adapted by permission of the author.

others and to avoid standing out from the crowd. A popular adage in Japan reminds children that "the nail that stands out gets pounded down." Hence, Markus and Kitayama assert that Asian youngsters typically learn to define themselves in terms of the groups they belong to. Their harmonious relations with others and their pride in group achievements become the basis for their sense of self-worth. Because their self-esteem does not hinge so much on personal strengths, they are less likely to emphasize their uniqueness. Consistent with this analysis, Markus and Kitayama report that Asian subjects tend to view themselves as more similar to their peers than American subjects do.

REVIEW of Key Learning Goals

12.23 The basic trait structure of personality may be much the same across cultures, as the Big Five traits usually emerge in cross-cultural studies. However, some cultural variability has been seen when researchers compare average trait scores for various cultural groups.

12.24 Researchers have measured countries' national character by asking participants to describe the typical member of their culture on rating forms. However, averaged test data collected from real individuals show that these perceptions of national character tend to be inaccurate stereotypes.

12.25 Markus and Kitayama assert that American culture fosters an independent conception of self as a unique individual who is separate from others. In contrast, Asian cultures foster an interdependent view of the self, as part of an interconnected social matrix.

Reflecting on the Chapter's Themes

Our discussion of culture and personality obviously highlighted the text's theme that people's behavior is influenced by their cultural heritage. This chapter has also been ideally suited for embellishing two other unifying themes: psychology's theoretical diversity and the idea that psychology evolves in a sociohistorical context.

No other area of psychology is characterized by as much theoretical diversity as the study of personality, where there are literally dozens of insightful theories. Some of this diversity exists because different theories attempt to explain different facets of behavior. However, much of this theoretical diversity reflects genuine disagreements on basic questions about personality. Some of these disagreements are apparent on pages 520–521, which present an Illustrated Overview of the ideas of Freud, Skinner, Rogers, and Eysenck, as representatives of the psychodynamic, behavioral, humanistic, and biological approaches to personality.

The study of personality also highlights the sociohistorical context in which psychology evolves. Personality theories have left many marks on modern culture. The theories of Freud, Adler, and Skinner have had an enormous impact on childrearing practices. The ideas of Freud and Jung have found their way into literature (influencing the portrayal of fictional characters) and the visual arts. For example, Freud's theory helped inspire surrealism's interest in the world of dreams (see **Figure 12.18** on the next page). Maslow's hierarchy of needs and Skinner's affirmation of the value of positive reinforcement have influenced approaches to management in the world of business and industry.

Key Learning Goals

12.26 Identify the three unifying themes highlighted in this chapter.

Cultural Heritage

Theoretical Diversity

Sociohistorical Context

Image not available due to copyright restrictions

Sociohistorical forces also leave their imprint on psychology. This chapter provided many examples of how personal experiences, prevailing attitudes, and historical events have contributed to the evolution of ideas in psychology. For example, Freud's pessimistic view of human nature and his emphasis on the dark forces of aggression were shaped to some extent by his exposure to the hostilities of World War I and prevailing anti-Semitic sentiments. And Freud's emphasis on sexuality was surely influenced by the Victorian climate of sexual repression that existed in his youth. Adler's views also reflected the social context in which he grew up. His interest in inferiority feelings and compensation appear to have sprung from his own sickly childhood and the difficulties he had to overcome. In a similar vein, we saw that both Rogers and Maslow had to resist parental pressures in order to pursue their career interests. Their emphasis on the need to achieve personal fulfillment may have originated in these experiences.

Progress in the study of personality has also been influenced by developments in other areas of psychology. For instance, the enterprise of psychological testing originally emerged out of efforts to measure intelligence. Eventually, however, the principles of psychological testing were applied to the challenge of measuring personality. In the upcoming Personal Application we discuss the logic and limitations of personality tests.

REVIEW of Key Learning Goals

12.26 The study of personality illustrates how psychology is characterized by great theoretical diversity. It also demonstrates how ideas in psychology are shaped by sociohistorical forces and how cultural factors influence psychological processes.

Understanding Personality Assessment

Key Learning Goals

12.27 Describe several prominent personality inventories, and evaluate the strengths and weaknesses of self-report inventories.

12.28 Describe two projective tests, and evaluate the strengths and weaknesses of projective testing.

12.29 Analyze the emerging role of the Internet in personality assessment.

Answer the following "true" or "false."

_____ **1** Responses to personality tests are subject to unconscious distortion.

_____ **2** The results of personality tests are often misunderstood.

_____ **3** Personality test scores should be interpreted with caution.

_____ **4** Personality tests serve many important functions.

If you answered "true" to all four questions, you earned a perfect score. Yes, personality tests are subject to distortion. Admittedly, test results are often misunderstood, and they should be interpreted cautiously. In spite of these problems, however, psychological tests can be quite useful.

Everyone engages in efforts to size up his or her own personality as well as that of others. When you think to yourself that "Mary Ann is shrewd and poised," or when you remark to a friend that "Carlos is timid and submissive," you're making personality assessments. In a sense, then, personality assessment is an ongoing part of daily life. Given the popular interest in personality assessment, it's not surprising that psy-

chologists have devised formal measures of personality.

Personality tests can be helpful in (1) making clinical diagnoses of psychological disorders, (2) vocational counseling, (3) personnel selection in business and industry, and (4) measuring specific personality traits for research purposes. Personality tests can be divided into two broad categories: *self-report inventories* and *projective tests*. In this Personal Application, we'll discuss some representative tests from both categories and discuss their strengths and weaknesses.

Self-Report Inventories 7a

Self-report inventories **are personality tests that ask individuals to answer a series of questions about their characteristic behavior.** The logic underlying this approach is simple: Who knows you better? Who has known you longer? Who has more access to your private feelings? We'll look at three examples of self-report scales, the MMPI, the 16PF, and the NEO Personality Inventory.

The MMPI

The most widely used self-report inventory is the Minnesota Multiphasic Personality Inventory (MMPI) (Butcher, 2005, 2006). The MMPI was originally designed to aid clinicians in the diagnosis of psychological disorders. It measures 10 personality traits that, when manifested to an extreme degree, are thought to be symptoms of disorders. Examples include traits such as paranoia, depression, and hysteria.

Are the MMPI clinical scales valid? That is, do they measure what they were designed to measure? Originally, it was assumed that the 10 clinical subscales would provide direct indexes of specific types of disorders. In other words, a high score on the depression scale would be indicative of depression, a high score on the paranoia scale would be indicative of a paranoid disorder, and so forth. However, research revealed that the relations between MMPI scores and various types of mental illness are much more complex than originally anticipated. People with most types of disorders show elevated scores on *several* MMPI subscales. This means that certain score *profiles* are indicative of specific disorders (see **Figure 12.19**). Thus, the interpretation of the MMPI is quite complicated. Nonetheless, the MMPI can be a helpful diagnostic tool for the clinician. The fact that the inventory has been translated into more than 115 languages is a testimonial to its usefulness (Adams & Culbertson, 2005).

The 16PF and NEO Personality Inventory 7a

Raymond Cattell (1957, 1965) set out to identify and measure the *basic dimensions* of the *normal* personality. He started with a previously compiled list of 4504 personal-

ity traits. This massive list was reduced to 171 traits by weeding out terms that were virtually synonyms. Cattell then used factor analysis to identify clusters of closely related traits and the factors underlying them. Eventually, he reduced the list of 171 traits to 16 *source traits*. The Sixteen Personality Factor (16PF) Questionnaire (Cattell, Eber, & Tatsuoka, 1970; Cattell, 2007) is a 187–item scale that assesses these 16 basic dimensions of personality, which are listed in **Figure 12.20** on the next page.

As we noted in the main body of the chapter, some theorists believe that only five trait dimensions are required to provide a full description of personality. This view has led to the creation of a relatively new test—the NEO Personality Inventory. Developed by Paul Costa and Robert McCrae (1985, 1992), the NEO Inventory is designed to measure the Big Five traits: neuroticism, extraversion, openness to experience, agreeableness, and conscientiousness. The NEO inventory is widely used in research and clinical work, and updated revisions of the scale have been released (McCrae & Costa, 2004, 2007). An example of a NEO profile (averaged from many respondents) was shown in our discussion of culture and personality (see **Figure 12.16**).

Strengths and Weaknesses of Self-Report Inventories

To appreciate the strengths of self-report inventories, consider how else you might
Figure 12.19

MMPI profiles. Scores on the 10 clinical scales of the MMPI are often plotted as shown here to create a profile for a client. The normal range for scores on each subscale is 50 to 65. People with disorders frequently exhibit elevated scores on several clinical scales rather than just one.

Figure 12.20

The Sixteen Personality Factor Questionnaire (16PF). Unlike the MMPI, Cattell's 16PF is designed to assess normal aspects of personality. The pairs of traits listed across from each other in the figure define the 16 factors measured by this self-report inventory. The profile shown is the average profile seen among a group of airline pilots who took the test.

inquire about an individual's personality. For instance, if you want to know how assertive someone is, why not just ask the person? Why administer an elaborate 50–item personality inventory that measures assertiveness? The advantage of the personality inventory is that it can provide a more objective and more precise estimate of the person's assertiveness, one that is better grounded in extensive comparative data based on information provided by many other respondents.

Of course, self-report inventories are only as accurate as the information that respondents provide. They are susceptible to several sources of error (Ben-Porath, 2003; Kline, 1995; Paulhus, 1991), including the following:

1. *Deliberate deception.* Some self-report inventories include many questions whose purpose is easy to figure out. This problem makes it possible for some respondents to intentionally fake particular personality traits (Rees & Metcalfe, 2003). Some studies suggest that deliberate faking is a serious problem when personality scales are used to evaluate job applicants (Birkeland et al., 2006), but other studies suggest that the problem is not all that significant (Hogan, Barrett, & Hogan, 2007).

2. *Social desirability bias.* Without realizing it, some people consistently respond to questions in ways that make them look good. The social desirability bias isn't a matter of deception so much as wishful thinking.

3. *Response sets.* A response set is a systematic tendency to respond to test items in a particular way that is unrelated to the content of the items. For instance, some people, called "yea-sayers," tend to agree with virtually every statement on a test. Other people, called "nay-sayers," tend to disagree with nearly every statement.

Test developers have devised a number of strategies to reduce the impact of deliberate deception, social desirability bias, and response sets (Berry, Wetter, & Baer, 1995; Lanyon & Goodstein, 1997). For instance, it's possible to insert a "lie scale" into a test to assess the likelihood that a respondent is engaging in deception. The best way to reduce the impact of social desirability bias is to identify items that are sensitive to this bias and drop them from the test. Problems with response sets can be reduced by systematically varying the way in which test items are worded. Although self-report inventories have some weaknesses, carefully constructed personality scales remain "an

indispensable tool for applied psychologists" (Hogan, 2005, p. 331).

Projective Tests 7a

Projective tests, which all take a rather indirect approach to the assessment of personality, are used extensively in clinical work. *Projective tests ask participants to respond to vague, ambiguous stimuli in ways that may reveal the subjects' needs, feelings, and personality traits.* The Rorschach test (Rorschach, 1921), for instance, consists of a series of ten inkblots. Respondents are asked to describe what they see in the blots. In the Thematic Apperception Test (TAT) (Murray, 1943), a series of pictures of simple scenes is presented to individuals who are asked to tell stories about what is happening in the scenes and what the characters are feeling. For instance, one TAT card shows a young boy contemplating a violin resting on a table in front of him (see **Figure 12.21** for another example).

The Projective Hypothesis 7a

The "projective hypothesis" is that ambiguous materials can serve as a blank screen onto which people project their character-

Image not available due to copyright restrictions

istic concerns, conflicts, and desires (Frank, 1939). Thus, a competitive person who is shown the TAT card of the boy at the table with the violin might concoct a story about how the boy is contemplating an upcoming musical competition at which he hopes to excel. The same card shown to a person high in impulsiveness might elicit a story about how the boy is planning to sneak out the door to go dirt-bike riding with friends.

The scoring and interpretation of projective tests is very complicated. Rorschach responses may be analyzed in terms of content, originality, the feature of the inkblot that determined the response, and the amount of the inkblot used, among other criteria. In fact, six different systems exist for scoring the Rorschach (Adams & Culbertson, 2005). TAT stories are examined in terms of heroes, needs, themes, and outcomes.

Strengths and Weaknesses of Projective Tests

Proponents of projective tests assert that the tests have two unique strengths. First, they are not transparent to respondents. That is,

the subject doesn't know how the test provides information to the tester. Hence, it may be difficult for people to engage in intentional deception (Groth-Marnat, 1997). Second, the indirect approach used in these tests may make them especially sensitive to unconscious, latent features of personality.

Unfortunately, the scientific evidence on projective measures is unimpressive (Garb, Florio, & Grove, 1998; Hunsley, Lee, & Wood, 2003). In a thorough review of the relevant research, Lilienfeld, Wood, and Garb (2000) conclude that projective tests tend to be plagued by inconsistent scoring, low reliability, inadequate test norms, cultural bias, and poor validity estimates. They also assert that, contrary to advocates' claims, projective tests are susceptible to some types of intentional deception (primarily, faking poor mental health). Based on their analysis, Lilienfeld and his colleagues argue that projective tests should be referred to as projective "techniques" or "instruments" rather than tests because "most of these techniques as used in daily clinical practice do not fulfill the traditional criteria for psychological tests" (p. 29). In spite of these problems, projective tests continue to be used by many clinicians. Although the questionable scientific status of these techniques is a very real problem, their continued popularity suggests that they yield subjective information that many clinicians find useful (Viglione & Rivera, 2003).

Personality Testing on the Internet

The emergence of the Internet has had a considerable impact on the process of personality assessment. Self-report inventories are increasingly being administered over the Internet by researchers, clinicians, and companies (Naglieri et al., 2004). Most of the widely used personality scales are available in an online format. The advantages of online testing are substantial (Buchanan, 2007). Tests can be completed quickly, with reduced labor costs, and the data flow directly into interpretive software. Online testing also allows test administrators to collect additional data that would not be available from a traditional paper-and-pencil test. For instance, they can track answer

changing and how long respondents ponder specific questions. Online testing also allows clinicians to deliver assessment services to rural clients who do not have access to local psychologists (Barak & Buchanan, 2004). Given all these advantages, Buchanan (2007, p. 450) notes that "it is easy to imagine a future where virtually all testing is conducted online."

Are there any disadvantages to online personality assessment? Well, there are issues that merit concern, but they appear to be manageable. The item content of some tests is closely guarded, so security is an issue for some tests (Naglieri et al., 2004). And when personality tests are used for hiring purposes, verifying the identity of the respondent is important. The chief theoretical issue is whether tests delivered online yield results that are equivalent to what is found when the same tests are administered in a paper-and-pencil format. For the most part, research suggests that online tests are equivalent to their offline counterparts, but this issue should be checked empirically whenever a specific test is migrated to an online format (Buchanan, 2007; Epstein & Klinkenberg, 2001). Overall, though, the future of online personality testing appears bright. That said, consumers should remember that the Internet is utterly unregulated, so one can find an abundance of pop psychology tests online that have no scientific or empirical basis (Naglieri et al., 2004).

REVIEW of Key Learning Goals

12.27 Self-report inventories ask subjects to describe themselves. The MMPI is a widely used inventory that measures pathological aspects of personality. The 16PF assesses 16 dimensions of the normal personality. The NEO personality inventory measures the Big Five personality traits. Self-report inventories are vulnerable to certain sources of error, including deception, the social desirability bias, and response sets.

12.28 Projective tests assume that subjects' responses to ambiguous stimuli reveal something about their personality. In the Rorschach test, respondents describe what they see in 10 inkblots, whereas subjects formulate stories about simple scenes when they take the TAT. While the projective hypothesis seems plausible, projective tests' reliability and validity are disturbingly low.

12.29 Self-report inventories are increasingly being administered over the Internet. The advantages of online testing are substantial, although there are concerns about security and test equivalence.

Hindsight in Everyday Analyses of Personality

Key Learning Goals

12.30 Understand how hindsight bias affects everyday analyses and theoretical analyses of personality.

Consider the case of two close sisters who grew up together: Lorena and Christina. Lorena grew into a frugal adult who is careful about spending her money, only shops when there are sales, and saves every penny she can. In contrast, Christina became an extravagant spender who lives to shop and never saves any money. How do the sisters explain their striking personality differences? Lorena attributes her thrifty habits to the fact that her family was so poor when she was a child that she learned the value of being careful with money. Christina attributes her extravagant spending to the fact that her family was so poor that she learned to really enjoy any money that she might have. Now, it *is* possible that two sisters could react to essentially the same circumstances quite differently, but the more likely explanation is that both sisters have been influenced by the *hindsight bias—the tendency to mold one's interpretation of the past to fit how events actually turned out.* We saw how hindsight can distort memory in Chapter 7. Here, we will see how hindsight tends to make everyone feel

as if he or she is a personality expert and how it creates interpretive problems even for scientific theories of personality.

The Prevalence of Hindsight Bias

Hindsight bias is *ubiquitous,* which means that it occurs in a variety of settings, with all sorts of people (Blank, Musch, & Pohl, 2007; Sanna & Schwarz, 2006). Most of the time, people are not aware of the way their explanations are skewed by the fact that the outcome is already known. The experimental literature on hindsight bias offers a rich array of findings on how the knowledge of an outcome biases the way people think about its causes (Fischhoff, 2007; Guilbault et al., 2004). For example, when college students were told the results of hypothetical experiments, each group of students could "explain" why the studies turned out the way they did, even though different groups were given opposite results to explain (Slovic & Fischhoff, 1977). The students believed that the results of the studies were obvious when they were told what the experimenter found, but when they were given only the information that was available before the outcome was known, it was not obvious at all. This bias is also called the "I knew it all along" effect because that is the typical refrain of people when they have the luxury of hindsight. Indeed, after the fact, people often act as if events that would have been difficult to predict had in fact been virtually *inevitable.* Looking back at the disintegration of the Soviet Union and the end of the Cold War, for instance, many people today act as though these events were bound to happen, but in reality these landmark events were predicted by almost no one. It appears that outcome knowledge warps judgments in two ways (Erdfelder, Brandt, & Broder, 2007). First, knowing

the outcome of an event impairs one's recall of earlier expectations about the event. Second, outcome knowledge shapes how people reconstruct their thinking about the event.

Hindsight bias shows up in many contexts. For example, when a couple announces that they are splitting up, many people in their social circle will typically claim they "saw it coming." When a football team loses in a huge upset, you will hear many fans claim, "I knew they were overrated and vulnerable." When public authorities make a difficult decision that leads to a disastrous outcome—such as officials' decision not to evacuate New Orleans in preparation for Hurricane Katrina until relatively late—many of the pundits in the press are quick to criticize, often asserting that only incompetent fools could have failed to foresee the catastrophe. Interestingly, people are not much kinder to themselves when they make ill-fated decisions. When individuals make tough calls that lead to negative results—such as buying a car that turns out to be a lemon, or investing in a stock that plummets—they often say things like, "Why did I ignore the obvious warning signs?" or "How could I be such an idiot?"

Hindsight and Personality

Hindsight bias appears to be pervasive in everyday analyses of personality. Think about it: If you attempt to explain why you are so suspicious, why your mother is so domineering, or why your best friend is so insecure, the starting point in each case will be the personality outcome. It would probably be impossible to reconstruct the past without being swayed by your knowledge of these outcomes. Thus, hindsight makes everybody an expert on personality, as we can all come up with plausible explanations for the personality traits of people we know well. Perhaps this is why Judith Harris (1998) ignited a firestorm of protest when she wrote a widely read book arguing that parents have relatively little effect

When public officials make tough decisions that backfire, critics are often quick to argue that the officials should have shown greater foresight. This type of hindsight bias has been apparent in discussions of whether New Orleans mayor Ray Nagin (at left) and other state and federal officials should have been more proactive in evacuating New Orleans when Hurricane Katrina loomed as a threat.

on their children's personalities beyond the genetic material that they supply.

In her book *The Nurture Assumption,* Harris summarizes behavioral genetics research and other evidence suggesting that family environment has surprisingly little impact on children's personality (see p. 515). As discussed in the main body of the chapter, there is room for debate on this complex issue (Kagan, 1998; Tavris, 1998), but our chief interest here is that Harris made a cogent, compelling argument in her book that attracted extensive coverage in the press, which generated an avalanche of commentary from angry parents who argued that *parents do matter.* For example, *Newsweek* magazine received 350 letters, mostly from parents who provided examples of how they thought they influenced their children's personalities. However, parents' retrospective analyses of their children's personality development have to be treated with great skepticism, as they are likely to be distorted by hindsight bias (not to mention the selective recall frequently seen in anecdotal reports).

Unfortunately, hindsight bias is so prevalent it also presents a problem for scientific theories of personality. For example, the spectre of hindsight bias has been raised in many critiques of psychoanalytic theory (Torrey, 1992). Freudian theory was originally built mainly on a foundation of case studies of patients in therapy. Obviously, Freudian therapists who knew what their patients' adult personalities were like probably went looking for the types of childhood experiences hypothesized by Freud (oral fixations, punitive toilet training, Oedipal conflicts, and so forth) in their efforts to explain their patients' personalities.

Another problem with hindsight bias is that once researchers know an outcome, more often than not they can fashion some plausible explanation for it. For instance, Torrey (1992) describes a study inspired by Freudian theory that examined breast-size preferences among men. The original hypothesis was that men who scored higher in dependence—thought to be a sign of oral fixation—would manifest a stronger preference for women with large breasts. When the actual results of the study showed just the opposite—that dependence was associated with a preference for smaller breasts—the finding was attributed to reaction formation on the part of the men. Instead of failing to support Freudian theory, the unexpected findings were simply reinterpreted in a way that was consistent with Freudian theory.

Hindsight bias also presents thorny problems for evolutionary theorists, who generally work backward from known outcomes to reason out how adaptive pressures in humans' ancestral past may have led to those outcomes (Cornell, 1997). Consider, for instance, evolutionary theorists' assertion that the Big Five traits are found to be fundamental dimensions of personality around the world because those specific traits have had major adaptive implications over the course of human history (Buss, 1995; Nettle, 2006). Their explanation makes sense, but what would have happened if some *other traits* had shown up in the Big Five? Would the evolutionary view have been weakened if dominance, or paranoia, or high sensation seeking had turned up in the Big Five? Probably not. With the luxury of hindsight, evolutionary theorists surely could have constructed plausible explanations for how these traits promoted reproductive success in the distant past. Thus, hindsight bias is a fundamental feature of human cognition, and the scientific enterprise is not immune to this problem.

Other Implications of "20/20 Hindsight"

Our discussion of hindsight has focused on its implications for thinking about personality, but there is ample evidence that hindsight can bias thinking in all sorts of domains. For example, consider the practice of obtaining second opinions on medical diagnoses. The doctor providing the second opinion usually is aware of the first physician's diagnosis, which creates a hindsight bias (Arkes et al., 1981). Second opinions would probably be more valuable if the doctors rendering them were not aware of previous diagnoses. Hindsight also has the potential to distort legal decisions in many types of cases where jurors evaluate defendants' responsibility for known outcomes, such as a failed surgery (Harley, 2007). For example, in trials involving allegations of negligence, jurors' natural tendency to think "how could they have failed to foresee this problem?" may exaggerate the appearance of negligence (LaBine & LaBine, 1996).

Hindsight bias is very powerful. The next time you hear of an unfortunate outcome to a decision made by a public official, carefully examine the way news reporters describe the decision. You will probably find that they believe that the disastrous outcome should have been obvious, because they can clearly see what went wrong after the fact. Similarly, if you find yourself thinking "Only a fool would have failed to anticipate this disaster" or "I would have foreseen this problem," take a deep breath and try to review the decision *using only information that was known at the time the decision was being made.* Sometimes good decisions, based on the best available information, can have terrible outcomes. Unfortunately, the clarity of "20/20 hindsight" makes it difficult for people to learn from their own and others' mistakes.

Table 12.3 Critical Thinking Skill Discussed in This Application

Skill	Description
Recognizing the bias in hindsight analysis	The critical thinker understands that knowing the outcome of events biases one's recall and interpretation of the events.

Key Ideas

The Nature of Personality

❚ The concept of personality explains the consistency in people's behavior over time and situations while also explaining their distinctiveness. The five-factor model has become the dominant conception of personality structure. The Big Five traits are predictive of everyday behavior, as well as important life outcomes.

Psychodynamic Perspectives

❚ Freud's psychoanalytic theory emphasizes the importance of the unconscious. Freud described personality structure in terms of three components—the id, ego, and superego—which are routinely involved in an ongoing series of internal conflicts.

❚ Freud theorized that conflicts centering on sex and aggression are especially likely to lead to anxiety. According to Freud, anxiety and other unpleasant emotions such as guilt are often warded off with defense mechanisms.

❚ Freud described a series of five stages of development: oral, anal, phallic, latency, and genital. Certain experiences during these stages can have lasting effects on adult personality.

❚ Jung's most innovative and controversial concept was the collective unconscious. Adler's individual psychology emphasizes how people strive for superiority to compensate for their feelings of inferiority.

❚ Overall, psychodynamic theories have produced many groundbreaking insights about the unconscious, the role of internal conflict, and the importance of early childhood experiences in personality development. However, psychodynamic theories have been criticized for their poor testability, their inadequate base of empirical evidence, and their male-centered views.

Behavioral Perspectives

❚ Behavioral theories view personality as a collection of response tendencies tied to specific stimulus situations. They assume that personality development is a lifelong process in which response tendencies are shaped and reshaped by learning, especially operant conditioning.

❚ Bandura's social cognitive theory focuses on how cognitive factors such as expectancies and self-efficacy regulate learned behavior. His concept of observational learning accounts for the acquisition of responses from models. Mischel has questioned the degree to which people display cross-situational consistency in behavior.

❚ Behavioral approaches to personality are based on rigorous research. They have provided ample insights into how environmental factors and learning mold personalities. The behaviorists have been criticized for their fragmented analysis of personality, radical behaviorism's dehumanizing view of human nature, and the modern dilution of the behavioral approach.

Humanistic Perspectives

❚ Humanistic theories are phenomenological and take an optimistic view of human potential. Rogers focused on the self-concept as the critical aspect of personality. Maslow theorized that psychological health depends on fulfilling one's need for self-actualization.

❚ Humanistic theories deserve credit for highlighting the importance of subjective views of oneself and for helping to lay the foundation for positive psychology. Humanistic theories lack a firm base of research, are difficult to put to an empirical test, and may be overly optimistic about human nature.

Biological Perspectives

❚ Contemporary biological theories stress the genetic origins of personality. Eysenck suggests that heredity influences individual differences in physiological functioning that affect how easily people acquire conditioned responses. Research on the personality resemblance of twins provides impressive evidence that genetic factors shape personality.

❚ Evolutionary theorists argue that the major dimensions of personality reflect humans' adaptive landscape. The biological approach has demonstrated that personality is partly heritable, but it has been criticized for its narrow focus on heritability and because it offers no systematic model of how physiology shapes personality.

A Contemporary Empirical Approach: Terror Management Theory

❚ Terror management theory proposes that self-esteem and belief in a cultural worldview shield people from the profound anxiety associated with their mortality.

Consistent with this analysis, increasing mortality salience leads people to make efforts to bolster their self-esteem and defend their worldviews. These defensive reactions are automatic and subconscious.

Culture and Personality

❚ Research suggests that the basic trait structure of personality may be much the same across cultures, as the Big Five traits usually emerge in cross-cultural studies. However, there are cultural variations in the mean level of some personality traits.

❚ Perceptions of national character appear to be inaccurate stereotypes. Markus and Kitayama assert that American culture fosters an independent conception of self, whereas Asian cultures foster an interdependent view of the self.

Reflecting on the Chapter's Themes

❚ The study of personality illustrates how psychology is characterized by great theoretical diversity. It also demonstrates how ideas in psychology are shaped by sociohistorical forces and how cultural factors influence psychological processes.

PERSONAL APPLICATION Understanding Personality Assessment

❚ Personality assessment is useful in clinical diagnosis, counseling, personnel selection, and research. Self-report measures, such as the MMPI, 16PF, and NEO Inventory, ask subjects to describe themselves. Self-report inventories are vulnerable to certain sources of error, including deception, the social desirability bias, and response sets.

❚ Projective tests, such as the Rorschach and TAT, assume that subjects' responses to ambiguous stimuli reveal something about their personality. While the projective hypothesis seems plausible, projective tests' reliability and validity are disturbingly low. Personality assessments are increasingly being administered over the Internet.

CRITICAL THINKING APPLICATION Hindsight in Everyday Analyses of Personality

❚ Hindsight bias often leads people to assert that "I knew it all along" in discussing outcomes that they did not actually predict. Thanks to hindsight, people can almost always come up with plausible-sounding explanations for known personality traits.

Key People

Alfred Adler (pp. 500–501)
Albert Bandura (pp. 504, 506)
Hans Eysenck (pp. 513–514)
Sigmund Freud (pp. 493–499)
Carl Jung (pp. 499–500)
Abraham Maslow (pp. 510–512)
Robert McCrae & Paul Costa
   (pp. 491–492)
Walter Mischel (pp. 507–508)
Carl Rogers (pp. 509–510)
B. F. Skinner (pp. 502–504)

1. Harvey Hedonist has devoted his life to the search for physical pleasure and immediate need gratification. Freud would say that Harvey is dominated by:
   A. his ego.
   B. his superego.
   C. his id.
   D. Bacchus.

2. Furious at her boss for what she considers to be unjust criticism, Tyra turns around and takes out her anger on her subordinates. Tyra may be using the defense mechanism of:
   A. displacement.
   B. reaction formation.
   C. identification.
   D. replacement.

3. Freud believed that most personality disturbances are due to:
   A. the failure of parents to reinforce healthy behavior.
   B. a poor self-concept resulting from excessive parental demands.
   C. unconscious and unresolved sexual conflicts rooted in childhood experiences.
   D. the exposure of children to unhealthy role models.

4. According to Alfred Adler, the prime motivating force in a person's life is:
   A. physical gratification.
   B. existential anxiety.
   C. striving for superiority.
   D. the need for power.

5. Which of the following learning mechanisms does B. F. Skinner see as being the major means by which behavior is learned?
   A. classical conditioning
   B. operant conditioning
   C. observational learning
   D. insight learning

6. Always having been a good student, Irving is confident that he will do well in his psychology course. According to Bandura's social cognitive theory, Irving would be said to have:
   A. strong feelings of self-efficacy.
   B. a sense of superiority.
   C. strong feelings of self-esteem.
   D. strong defense mechanisms.

7. Which of the following approaches to personality is least deterministic?
   A. the humanistic approach
   B. the psychoanalytic approach
   C. Skinner's approach
   D. the behavioral approach

8. Which of the following did Carl Rogers believe fosters a congruent self-concept?
   A. conditional love
   B. appropriate role models
   C. immediate-need gratification
   D. unconditional love

9. The strongest support for the theory that personality is heavily influenced by genetics is provided by strong personality similarity between:
   A. identical twins reared together.
   B. identical twins reared apart.
   C. fraternal twins reared together.
   D. nontwins reared together.

10. Which of the following is the best way to regard heritability estimates?
    A. as reliable but not necessarily valid estimates
    B. as ballpark estimates of the influence of genetics
    C. as accurate estimates of the influence of genetics
    D. as relatively useless estimates of the influence of genetics

11. Research on terror management theory has shown that increased mortality salience leads to all of the following except:
    A. increased striving for self-esteem.
    B. more stereotypic thinking about minorities.
    C. more negative reactions to people who criticize one's country.
    D. reduced respect for cultural icons.

12. When English language personality scales have been translated and administered in other cultures:
    A. the trait structure of personality has turned out to be dramatically different.
    B. the usual Big Five traits have emerged from the factor analyses.
    C. the personality scales have proven useless.
    D. a seven-factor solution has usually emerged from the factor analyses.

13. In which of the following cultures is an independent view of the self most likely to be the norm?
    A. China
    B. Japan
    C. Africa
    D. United States

14. Which of the following is *not* a shortcoming of self-report personality inventories?
    A. The accuracy of the results is a function of the honesty of the respondent.
    B. Respondents may attempt to answer in a way that makes them look good.
    C. There is sometimes a problem with "yea-sayers" or "nay-sayers."
    D. They are objective measures that are easy to administer and score.

15. In *The Nurture Assumption,* Judith Harris argues that the evidence indicates that family environment has _____ on children's personalities.
    A. largely positive effects
    B. largely negative effects
    C. surprisingly little effect
    D. a powerful effect

STRESS, COPING, AND HEALTH

You're in your car headed home from school with a classmate. Traffic is barely moving. A radio report indicates that the traffic jam is only going to get worse. You groan audibly as you fiddle impatiently with the radio dial. Another motorist narrowly misses your fender trying to cut into your lane. Your pulse quickens as you shout insults at the unknown driver, who can't even hear you. You think about the term paper you have to work on tonight. Your stomach knots up as you recall all the crumpled drafts you tossed into the wastebasket last night. If you don't finish that paper soon, you won't be able to find any time to study for your math test, not to mention your biology quiz. Suddenly, you remember that you promised the person you're dating that the two of you would get together tonight. There's no way. Another fight looms on the horizon. Your classmate asks how you feel about the tuition increase that the college announced yesterday. You've been trying not to think about it. You're already in debt up to your ears. Your parents are bugging you about changing schools, but you don't want to leave your friends. Your heartbeat quickens as you contemplate the debate you're sure to have with your parents. You feel wired with tension as you realize that the stress in your life never seems to let up.

Many circumstances can create stress. It comes in all sorts of packages: big and small, pretty and ugly, simple and complex. All too often, the package comes as a surprise. In this chapter we'll try to sort out these packages. We'll discuss the nature of stress, how people cope with stress, and the potential effects of stress.

Our examination of the relationship between stress and physical illness will lead us into a broader discussion of the psychology of health. The way people in health professions think about physical illness has changed considerably in the past 30 years. The traditional view of physical illness as a purely biological phenomenon has given way to a biopsychosocial model of illness (Friedman & Adler, 2007). **The *bio-psychosocial model* holds that physical illness is caused by a complex interaction of biological, psychological, and sociocultural factors.** This model does not suggest that biological factors are unimportant. It simply asserts that these factors operate in a psychosocial context that is also influential.

What has led to this shift in thinking? In part, it's a result of changing patterns of illness. Prior to the 20th century, the principal threats to health were *contagious diseases* caused by infectious agents—diseases such as smallpox, typhoid fever, diphtheria, yellow fever, malaria, cholera, tuberculosis, and polio. Today,

Figure 13.1

Changing patterns of illness. Historical trends in the death rates for various diseases reveal that contagious diseases (shown in blue) have declined as a threat to health. However, the death rates for stress-related chronic diseases (shown in red) have remained quite high. The pie chart (inset) shows the results of these trends: Three chronic diseases (heart disease, cancer, and stroke) account for about 55% of all deaths. Although these chronic diseases remain the chief threat to health in modern societies, it is interesting to note that deaths from heart disease have declined considerably since the 1980s. Many experts attribute much of this decline to improved health habits (Brannon & Feist, 2007), which demonstrates the important link between behavior and health. (Based on data from *National Vital Statistics Reports,* 2008, Volume 56, Number 10)
none of these diseases is among the leading killers in the United States. They were tamed by improvements in nutrition, public hygiene, sanitation, and medical treatment (Grob, 1983). Unfortunately, the void left by contagious diseases has been filled all too quickly by *chronic diseases* that develop gradually, such as heart disease, cancer, and stroke (see **Figure 13.1**). Psychosocial factors, such as stress and lifestyle, play a large role in the development of these chronic diseases. The growing recognition that psychological factors influence physical health eventually led to the emergence of a new specialty in psychology, called *health psychology* (Friedman & Adler, 2007). **Health psychology is concerned with how psychosocial factors relate to the promotion and maintenance of health and with the causation, prevention, and treatment of illness.** In the second half of this chapter, we'll explore this new domain of psychology. In the Personal Application, we'll focus on strategies for enhancing stress management, and in the Critical Thinking Application we'll discuss strategies for improving health-related decision making.

The Nature of Stress

The word *stress* has been used in different ways by different theorists. We'll define *stress* **as any circumstances that threaten or are perceived to threaten one's well-being and that thereby tax one's coping abilities.** The threat may be to immediate physical safety, long-range security, self-esteem, reputation, peace of mind, or many other things that one values. Stress is a complex concept, so let's explore a little further.

Stress as an Everyday Event

The word *stress* tends to spark images of overwhelming, traumatic crises. People may think of tornadoes, hurricanes, floods, and earthquakes. Undeniably, major disasters of this sort are extremely stressful events. Studies conducted in the aftermath of natural disasters typically find elevated rates of psychological problems and physical illness in the communities affected by these disasters (Stevens, Raphael, & Dobson, 2007; van Griensven et al., 2007; Weisler, Barbee, & Townsend, 2007). However, these unusual events are only a small part of what constitutes stress. Many everyday events, such as waiting in line, having car trouble, shopping for Christmas presents, misplacing your checkbook, and staring at bills you can't pay, are also stressful. Researchers have found that everyday problems and the minor nuisances

of life are also important forms of stress (Almeida, 2005; Kohn, Lafreniere, & Gurevich, 1991).

You might guess that minor stresses would produce minor effects, but that isn't necessarily true. Richard Lazarus and his colleagues, who developed a scale to measure everyday hassles, have shown that routine hassles may have significant harmful effects on mental and physical health (Delongis, Folkman, & Lazarus, 1988). Other investigators, working with different types of samples and different measures of hassles, have also found that everyday hassles are predictive of impaired mental and physical health (Chang & Sanna, 2003; Sher, 2003). Why would minor hassles be so troublesome? The answer isn't entirely clear yet, but it may be because of the *cumulative* nature of stress (Seta, Seta, & McElroy, 2002). Stress adds up. Routine stresses at home, at school, and at work might be fairly benign individually, but collectively they could create great strain.

Appraisal: Stress Lies in the Eye of the Beholder

The experience of feeling stressed depends on what events one notices and how one chooses to appraise or interpret them (Lazarus, 1999; Semmer, McGrath, & Beehr, 2005). Events that are stressful for one person may evoke little or no stress response from another person (Steptoe, 2007). For example, many people find flying in an airplane somewhat stressful, but frequent fliers may not be bothered at all. Some people enjoy the excitement of going out on a date with someone new; others find the uncertainty terrifying.

Often, people aren't very objective in their appraisals of potentially stressful events. A study of hospitalized patients awaiting surgery showed only a slight correlation between the objective seriousness of a person's upcoming surgery and the amount of fear experienced by the patients (Janis, 1958). Clearly, some people are more prone than others to feel threatened by life's difficulties. A number of studies have shown that anxious, neurotic people report more stress than others (Cooper & Bright, 2001; Watson, David, & Suls, 1999), as do people who are relatively unhappy (Cacioppo et al., 2008). Thus, stress lies in the eye (actually, the mind) of the beholder. People's appraisals of stressful events are highly subjective.

Major Types of Stress   11f

An enormous variety of events can be stressful for one person or another. To achieve a better understanding of stress, theorists have tried to analyze the nature of stressful events and divide them into subtypes. One sensible distinction involves differentiating between *acute stressors and chronic stressors* (Dougall & Baum, 2001; Stowell, 2008). ***Acute stressors* are threatening events that have a relatively short duration and a clear endpoint.** Examples would include having an encounter with a belligerent drunk, dealing with the challenge of a major exam, or having your home threatened by severe flooding. ***Chronic stressors* are threatening events that have a relatively long duration and no readily apparent time limit.** Examples would include persistent financial strains produced by huge credit card debts, ongoing pressures from a hostile boss at work, or the demands of caring for a sick family member over a period of years.

None of the proposed schemes for classifying stressful events has turned out to be altogether satisfactory. Classifying stressful events into nonintersecting categories is virtually impossible. Although this problem presents conceptual headaches for researchers, it need not prevent us from describing four major types of stress: frustration, conflict, change, and pressure. As you read about each of them, you'll surely recognize some familiar adversaries.

Frustration   11f

I had a wonderful relationship with a nice man for three months. One day when we planned to spend the entire day together, he called and said he wouldn't be meeting me and that he had decided to stop seeing me. I cried all morning. The grief was like losing someone through death. I still hurt, and I wonder if I'll ever get over him.

This scenario illustrates frustration. As psychologists use the term, ***frustration* occurs in any situation in which the pursuit of some goal is thwarted.** In essence, you experience frustration when you want something and you can't have it. Everyone has to deal with frustration virtually every day. Traffic jams and difficult daily commutes, for instance, are a routine source of frustration that can elicit anger and physical symptoms (Evans & Wener, 2006; Rasmussen, Knapp, & Garner, 2000), leading Schaefer (2005) to claim that "each added travel minute correlates with an increase in health problems" (p. 14). Fortunately, many frustrations are brief and insignificant. You may be quite upset when you go to a repair shop to pick up your ailing DVD player and find that it hasn't been fixed as promised. However, a week later you'll probably have your DVD player back, and the frustration will be forgotten.

Of course, some frustrations can be sources of significant stress. Failures and losses are two common kinds of frustration that are often highly stressful.

Richard Lazarus

"We developed the Hassle Scale because we think scales that measure major events miss the point. The constant, minor irritants may be much more important than the large, landmark changes."

The Web's Stress Management & Emotional Wellness Page

Ernesto Randolfi (Montana State University) has gathered a comprehensive set of resources dealing with stress management. Topics covered include cognitive restructuring, relaxation techniques, and stress in the workplace and in college life.

Everyone fails in at least some of his or her endeavors. Some people make failure almost inevitable by setting unrealistically high goals for themselves. For example, many business executives tend to forget that for every newly appointed vice president in the business world, there are dozens of middle-level executives who don't get promoted. Losses can be especially frustrating, because people are deprived of something that they're accustomed to having. For example, few things are more frustrating than losing a dearly loved boyfriend, girlfriend, spouse, or parent.

Conflict 11f

Should I or shouldn't I? I became engaged at Christmas. My fiance surprised me with a ring. I knew if I refused the ring he would be terribly hurt and our relationship would suffer. However, I don't really know whether or not I want to marry him. On the other hand, I don't want to lose him either.

Like frustration, conflict is an unavoidable feature of everyday life. The perplexing question "Should I or shouldn't I?" comes up countless times in everyone's life. **Conflict occurs when two or more incompatible motivations or behavioral impulses compete for expression.** Conflicts come

Approach-approach

+ Tennis		+ Racquetball
+ Pizza		+ Spaghetti
+ Blue sweater		+ Gray jacket

Avoidance-avoidance

| − Unemployment | | − Degrading job |
| − Painful backache | | − Surgery |

Approach-avoidance

| + Date with an attractive person |
| − Rejection |
| + Investment returns |
| − Loss of capital |

Figure 13.2

Types of conflict. Psychologists have identified three basic types of conflict. In approach-approach and avoidance-avoidance conflicts, a person is torn between two goals. In an approach-avoidance conflict, only one goal is under consideration, but it has both positive and negative aspects.

in three types, which were originally described by Kurt Lewin (1935) and investigated extensively by Neal Miller (1944, 1959). These three basic types of conflict—approach-approach, avoidance-avoidance, and approach-avoidance—are diagrammed in **Figure 13.2**.

In an **approach-approach conflict a choice must be made between two attractive goals.** The problem, of course, is that you can choose just one of the two goals. For example: You have a free afternoon; should you play tennis or racquetball? You can't afford both—should you buy the blue sweater or the gray jacket? Among the three kinds of conflict, the approach-approach type tends to be the least stressful. People don't usually stagger out of restaurants exhausted by the stress of choosing which of several appealing entrees to eat. Nonetheless, approach-approach conflicts over important issues may sometimes be troublesome. If you're torn between two appealing college majors or two attractive boyfriends, you may find the decision-making process quite stressful, since whichever alternative is not chosen represents a loss of sorts.

In an **avoidance-avoidance conflict a choice must be made between two unattractive goals.** Forced to choose between two repelling alternatives, you are, as they say, "caught between a rock and a hard place." For example, should you continue to collect unemployment checks, or should you take that degrading job at the car wash? Or suppose you have painful backaches. Should you submit to surgery that you dread, or should you continue to live with the back pain? Obviously, avoidance-avoidance conflicts are most unpleasant and highly stressful.

In an **approach-avoidance conflict a choice must be made about whether to pursue a single goal that has both attractive and unattractive aspects.** For instance, imagine that you're offered a career promotion that will mean a large increase in pay, but you'll have to move to a city where you don't want to live. Approach-avoidance conflicts are common and can be quite stressful. Any time you have to take a risk to pursue some desirable outcome, you're likely to find yourself in an approach-avoidance conflict. Approach-avoidance conflicts often produce *vacillation.* That is, you go back and forth, beset by indecision. You decide to go ahead, then you decide not to, then you decide to go ahead again. Humans are not unique in this respect. Many years ago, Neal Miller (1944) observed the same vacillation in his groundbreaking research with rats. He created approach-avoidance conflicts in hungry rats by alternately feeding and shocking them at one end of a runway

apparatus. Eventually, these rats tended to hover near the center of the runway, alternately approaching and retreating from the goal box at the end of the alley.

Change

11f

After my divorce, I lived alone for four years. Six months ago I married a wonderful woman who has two children from her previous marriage. My biggest stress is suddenly having to adapt to living with three people instead of by myself. I was pretty set in my ways. I had certain routines. Now everything is chaos. I love my wife and I'm fond of the kids. They're not really doing anything wrong. But my house and my life just aren't the same, and I'm having trouble dealing with it all.

It has been proposed that life changes, such as a change in marital status, represent a key type of stress. *Life changes* **are any significant alterations in one's living circumstances that require readjustment.** The importance of life changes was first demonstrated by Thomas Holmes, Richard Rahe, and their colleagues in the 1960s (Holmes & Rahe, 1967; Rahe & Arthur, 1978). Theorizing that stress might make people more vulnerable to illness, they interviewed thousands of tuberculosis patients to find out what kinds of events had preceded the onset of their disease. Surprisingly, the most frequently cited events were not uniformly negative. There were plenty of aversive events, of course, but there were also many seemingly positive events, such as getting married, having a baby, and getting promoted.

Why would positive events, such as moving to a nicer home, produce stress? According to Holmes and Rahe, it's because they produce *change.* In their view, changes in personal relationships, changes

at work, changes in finances, and so forth can be stressful even when the changes are welcomed.

Based on this analysis, Holmes and Rahe (1967) developed the Social Readjustment Rating Scale (SRRS) to measure life change as a form of stress. The scale assigns numerical values to 43 major life events. These values are supposed to reflect the magnitude of the readjustment required by each change (see Table 13.1 on the next page). In using the scale, respondents are asked to indicate how often they experienced any of these 43 events during a certain time period (typically, the past year). The numbers associated with each event checked are then added. This total is an index of the amount of change-related stress the person has recently experienced.

The SRRS and similar scales based on it have been used in over 10,000 studies by researchers all over the world (Dohrenwend, 2006). Overall, these studies have shown that people with higher scores on the SRRS tend to be more vulnerable to many kinds of physical illness and to many types of psychological problems as well (Derogatis & Coons, 1993; Scully, Tosi, & Banning, 2000; Surtees & Wainwright, 2007). These results have attracted a great deal of attention, and the SRRS has been reprinted in many popular newspapers and magazines. The attendant publicity has led to the widespread conclusion that life change is inherently stressful.

More recently, however, experts have criticized the research on the connection between life events and health, citing problems with the methods used and raising questions about the meaning of the findings (Dohrenwend, 2006; Monroe, 2008; Wethington, 2007). At this point, it's a key interpretive issue that concerns us. Many critics have argued that the SRRS does not measure *change* exclusively. The main

Table 13.1 Social Readjustment Rating Scale

Life Event	Mean Value	Life Event	Mean Value
Death of a spouse	100	Change in responsibilities at work	29
Divorce	73	Son or daughter leaving home	29
Marital separation	65	Trouble with in-laws	29
Jail term	63	Outstanding personal achievement	28
Death of a close family member	63	Spouse begins or stops work	26
Personal injury or illness	53	Begin or end school	26
Marriage	50	Change in living conditions	25
Fired at work	47	Revision of personal habits	24
Marital reconciliation	45	Trouble with boss	23
Retirement	45	Change in work hours or conditions	20
Change in health of family member	44	Change in residence	20
Pregnancy	40	Change in school	20
Sex difficulties	39	Change in recreation	19
Gain of a new family member	39	Change in church activities	19
Business readjustment	39	Change in social activities	18
Change in financial state	38	Mortgage or loan for lesser purchase	
Death of a close friend	37	(car, TV, etc.)	17
Change to a different line of work	36	Change in sleeping habits	16
Change in number of arguments with		Change in number of family get-togethers	15
spouse	35	Change in eating habits	15
Mortgage or loan for major purchase		Vacation	13
(home, etc.)	31	Christmas	12
Foreclosure of mortgage or loan	30	Minor violations of the law	11

problem is that the list of life changes on the SRRS is dominated by events that are clearly negative or undesirable (death of a spouse, being fired from a job, and so on). These negative events probably generate great frustration. Although there are some positive events on the scale, it turns out that negative life events cause most of the stress tapped by the SRRS (McLean & Link, 1994; Turner & Wheaton, 1995). Thus, it has become apparent that the SRRS assesses a wide range of stressful experiences, not just life change. At present, there's little reason to believe that change is inherently or inevitably stressful. Undoubtedly, some life changes may be quite challenging, but others may be quite benign.

Pressure   11f

My father questioned me at dinner about some things I didn't want to talk about. I know he doesn't want to hear my answers, at least not the truth. My father told me when I was little that I was his favorite because I was "pretty near perfect." I've spent my life trying to keep up that image, even though it's obviously not true. Recently, he has begun to realize this, and it's made our relationship very strained and painful.

At one time or another, most people have remarked that they're "under pressure." What does this term mean? **Pressure involves expectations or demands that one behave in a certain way.** You are under pressure to *perform* when you're expected to execute tasks and responsibilities quickly, effi-

ciently, and successfully. For example, salespeople are usually under pressure to move lots of merchandise. Professors at research institutions are often under pressure to publish in prestigious journals. Stand-up comedians are under intense pressure to make people laugh. Pressures to *conform* to others' expectations are also common in our lives. People in the business world are expected to dress in certain ways. Suburban homeowners are expected to keep their lawns well manicured. Teenagers are expected to adhere to their parents' values and rules.

Although widely discussed by the general public, the concept of pressure has received scant attention from researchers. However, Weiten (1988b, 1998) has devised a scale to measure pressure as a form of life stress. It assesses self-imposed pressure, pressure from work and school, and pressure from family relations, peer relations, and intimate relations. In research with this scale, a strong relationship has been found between pressure and a variety of psychological symptoms and problems. In fact, pressure has turned out to be more strongly related to measures of mental health than the SRRS and other established measures of stress (see **Figure 13.3**).

Recent research suggests that pressure related to academic pursuits may actually undermine academic performance and lead to problematic escape behaviors such as drinking (Kaplan, Liu, & Kaplan, 2005; Kieffer, Cronin, & Gawet, 2006). We tend to think of pressure as something imposed on us by outside forces. However, studies of high school and college students

Pressure comes in two varieties: pressure to perform and pressure to conform. For example, standup comedians are under intense pressure to make audiences laugh (pressure to perform), whereas corporate employees are often expected to dress in certain ways (pressure to conform).

find that *pressure is often self-imposed* (Kouzma & Kennedy, 2004; Misra & Castillo, 2004). For example, you might sign up for extra classes to get through school quickly. Or you might actively seek time-consuming leadership responsibilities to impress friends or to build your resume. People frequently put pressure on themselves to get good grades or to rapidly climb the corporate ladder. Actually, self-imposed stress is not unique to pressure. Research suggests that other forms of stress can also be self-generated (Roberts & Ciesla, 2007). One implication of this reality is that people might have more control over a substantial portion of the stress in their lives than they realize.

Figure 13.3

Pressure and psychological symptoms. A comparison of pressure and life change as sources of stress suggests that pressure may be more strongly related to mental health than change is. In one study, Weiten (1988b) found a correlation of .59 between scores on the Pressure Inventory (PI) and symptoms of psychological distress. In the same sample, the correlation between SRRS scores and psychological symptoms was only .28.

REVIEW of Key Learning Goals

13.1 Stress involves circumstances and experiences that are perceived as threatening. Stress is a common, everyday event, and even seemingly minor stressors, such as daily hassles, can be problematic. To a large degree, stress is subjective and lies in the eye of the beholder. People's appraisals of events determine what they find stressful.

13.2 Acute stressors have a short duration and clear endpoint, whereas chronic stressors have a relatively long duration. Major types of stress include frustration, conflict, change, and pressure. Frustration occurs when an obstacle prevents one from attaining some goal.

13.3 The three principal types of conflict are approach-approach, avoidance-avoidance, and approach-avoidance. The third type is especially stressful. Vacillation is a common response to approach-avoidance conflict.

13.4 A large number of studies with the SRRS suggest that life change is stressful. Although this may be true, it is now clear that the SRRS is a measure of general stress rather than just change-related stress. Two kinds of pressure (to perform and conform) also appear to be stressful.

concept check 13.2

Recognizing Sources of Stress

Check your understanding of the major sources of stress by indicating which type or types of stress are at work in each of the following examples. Bear in mind that the four basic types of stress are not mutually exclusive. There's some potential for overlap, so a specific experience might include both change and pressure, for instance. The answers are in Appendix A.

Examples

_____ 1. Marie is late for an appointment but is stuck in line at the bank.

_____ 2. Tamika decides that she won't be satisfied unless she gets straight A's this year.

_____ 3. Jose has just graduated from business school and has taken an exciting new job.

_____ 4. Morris has just been fired from his job and needs to find another.

Types of stress

a. frustration

b. conflict

c. change

d. pressure

People's response to stress is complex and multidimensional. Stress affects the individual at several levels. Consider again the chapter's opening scenario, in which you're driving home in heavy traffic and thinking about overdue papers, tuition increases, and parental pressures. Let's look at some of the reactions that were mentioned. When you groan in reaction to the traffic report, you're experiencing an *emotional response* to stress, in this case annoyance and anger. When your pulse quickens and your stomach knots up, you're exhibiting *physiological responses* to stress. When you shout insults at another driver, your verbal aggression is a *behavioral response* to the stress at hand. Thus, we can analyze a person's reactions to stress at three levels: (1) emotional responses, (2) physiological responses, and (3) behavioral responses. **Figure 13.4**, which diagrams these three levels of response, provides an overview of the stress process.

Emotional Responses   11g

When people are under stress, they often react emotionally. Studies that have tracked stress and mood on a daily basis have found intimate relationships between the two (Affleck et al., 1994; van Eck, Nicolson, & Berkhof, 1998).

Emotions Commonly Elicited   11g

No simple one-to-one connections have been found between certain types of stressful events and particular emotions. However, researchers *have* begun to uncover some strong links between specific *cognitive reactions to stress* (appraisals) and specific emotions (Smith & Lazarus, 1993). For example, self-blame tends to lead to guilt, helplessness to sadness, and so forth. Although many emotions can be evoked by stressful events, some are certainly more likely than others. Common responses to stress typically occur along three dimensions of emotion: (a) annoyance, anger, and rage, (b) apprehension, anxiety, and fear, and (c) dejection, sadness and grief (Lazarus, 1993).

Investigators have tended to focus heavily on the connection between stress and negative emotions, but research shows that positive emotions also occur during periods of stress (Folkman, 1997, 2008; Zautra et al., 2005). Although this finding seems counterintuitive, researchers have found that people experience a diverse array of pleasant emotions even while enduring dire circumstances. Consider, for example, a recent study that examined subjects' emotional functioning early in 2001 and again in the weeks following the 9/11 terrorist attacks in the United States (Fredrickson et al., 2003). Like most U.S. citizens, the participants reported many negative emotions in the aftermath of 9/11, including anger, sadness, and fear. However, within this "dense cloud of anguish" positive emotions also emerged. For example, people felt gratitude for the safety of their loved ones; many took stock and counted their blessings; and quite a few reported renewed love for their friends and family. Fredrickson et al. (2003) also found that the frequency of pleasant emotions correlated positively with a measure of subjects' resilience, whereas the frequency of unpleasant emotions correlated nega-

Figure 13.4

Overview of the stress process. A potentially stressful event, such as a major exam, elicits a subjective appraisal of how threatening the event is. If the event is viewed with alarm, the stress may trigger emotional, physiological, and behavioral reactions, as people's response to stress is multidimensional.

Potentially stressful objective events
A major exam, a big date, trouble with one's boss, or a financial setback, which may lead to frustration, conflict, change, or pressure

Subjective cognitive appraisal
Personalized perceptions of threat, which are influenced by familiarity with the event, its controllability, its predictability, and so on

Emotional response
Annoyance, anger, anxiety, fear, dejection, grief

Physiological response
Autonomic arousal, hormonal fluctuations, neurochemical changes, and so on

Behavioral response
Coping efforts, such as lashing out at others, blaming oneself, seeking help, solving problems, and releasing emotions

tively with resilience. Thus, contrary to common sense, positive emotions do *not* vanish during times of severe stress. Moreover, these positive emotions appear to play a key role in helping people bounce back from the difficulties associated with stress (Tugade & Fredrickson, 2004).

How do positive emotions promote resilience in the face of stress? Barbara Fredrickson's (2001, 2005, 2006) *broaden-and-build theory of positive emotions* can shed light on this question. First, positive emotions alter people's mindsets, broadening their scope of attention and increasing their creativity and flexibility in problem solving. Second, positive emotions can undo the lingering effects of negative emotions, and thus short-circuit the potentially damaging physiological responses to stress that we will discuss momentarily. Third, positive emotions can promote rewarding social interactions that help to build valuable social support, enhanced coping strategies, and other enduring personal resources.

Consistent with Fredrickson's model, recent research suggests that positive emotions widen people's scope of attention (Fredrickson & Branigan, 2005), promote healthy coping responses (Folkman, 2008), initiate upward spirals in emotional well-being (Burns et al., 2008), and facilitate flourishing mental health (Fredrickson & Losada, 2005). Studies have also found an association between positive emotion and lower levels of stress hormones (Steptoe et al., 2007) and reduced mortality in some populations (Pressman & Cohen, 2005).

One particularly interesting finding has been that a positive emotional style is associated with an enhanced immune response (Cohen & Pressman, 2006). For example, in a study by Sheldon Cohen and colleagues (2006), healthy volunteers were given nasal drops containing either a rhinovirus (cold virus) or flu virus and were carefully monitored for illness while living in quarantine conditions. The results showed that participants with a positive emotional style were less likely to develop an illness after exposure to either virus. Thus, it appears that the benefits of positive emotions may be more diverse and more far-reaching than widely appreciated.

Effects of Emotional Arousal   11g

Emotional responses are a natural and normal part of life. Even unpleasant emotions serve important purposes. Like physical pain, painful emotions can serve as warnings that one needs to take action. However, strong emotional arousal can also interfere with efforts to cope with stress. For example, there is evidence that high emotional arousal can interfere with attention and memory retrieval and can impair judgment and decision making (Janis, 1993; Lupien & Maheu, 2007; Mandler, 1993).

Although emotional arousal may hurt coping efforts, that isn't *necessarily* the case. The *inverted-U hypothesis* predicts that task performance should improve with increased emotional arousal—up to a point, after which further increases in arousal become disruptive and performance deteriorates (Anderson, 1990; Mandler, 1993). This idea is referred to as the inverted-U hypothesis because when performance is plotted as a function of arousal, the resulting graphs approximate an upside-down U (see **Figure 13.5**). In these graphs, the level of arousal at which performance peaks is characterized as the *optimal level of arousal* for a task.

This optimal level appears to depend in part on the complexity of the task at hand. The conventional wisdom is that *as tasks become more complex, the optimal level of arousal (for peak performance) tends to decrease.* This relationship is depicted in **Figure 13.5**. As you can see, a fairly high level of arousal should

Figure 13.5
Arousal and performance. Graphs of the relationship between emotional arousal and task performance tend to resemble an inverted U, as increased arousal is associated with improved performance up to a point, after which higher arousal leads to poorer performance. The optimal level of arousal for a task depends on the complexity of the task. On complex tasks, a relatively low level of arousal tends to be optimal. On simple tasks, however, performance may peak at a much higher level of arousal.
Level of task complexity

Simple — Medium — Complex

Performance level (Low / High) vs. Level of arousal (Low / High)

Optimal level of arousal

Hans Selye

"There are two main types of human beings: 'racehorses,' who thrive on stress and are only happy with a vigorous, fast-paced lifestyle; and 'turtles,' who in order to be happy require peace, quiet, and a generally tranquil environment."

be optimal on simple tasks that do not require complicated reasoning (such as driving 8 hours to help a friend in a crisis). However, performance should peak at a lower level of arousal on complex tasks (such as making a major decision in which you have to weigh many factors). Although doubts have been raised about the validity of the inverted-U hypothesis (Hancock & Ganey, 2003), it provides a plausible model of how emotional arousal could have either beneficial or disruptive effects on coping, depending on the nature of the stressful demands.

Physiological Responses 11g

As we just discussed, stress frequently elicits strong emotional responses. Now we'll look at the important physiological changes that often accompany these responses.

The Fight-or-Flight Response

Walter Cannon (1932) was one of the first theorists to describe the fight-or-flight response. **The *fight-or-flight response* is a physiological reaction to threat in which the autonomic nervous system mobilizes the organism for attacking (fight) or fleeing (flight) an enemy.** As you may recall from Chapter 3, the *autonomic nervous system (ANS)* controls blood vessels, smooth muscles, and glands. The fight-or-flight response is mediated by the *sympathetic division* of the ANS (McCarty, 2007). In one experiment, Cannon studied the fight-or-flight response in cats by confronting them with dogs. Among other things, he noticed an immediate acceleration in their breathing and heart rate and a reduction in their digestive processes.

The physiological arousal associated with the fight-or-flight response is also seen in humans. In a sense, this automatic reaction is a "leftover" from humanity's evolutionary past. It's clearly an adaptive response in the animal kingdom, where the threat of predators often requires a swift response of fighting or fleeing. But in our modern world, the fight-or-flight response may be less adaptive for human functioning than it was thousands of generations ago (Nesse, Bhatnagar, & Young, 2007). Most human stresses can't be handled simply through fight or flight. Work pressures, marital problems, and financial difficulties require far more complex responses.

Shelley Taylor and her colleagues (Taylor 2002, 2006; Taylor et al., 2000) have questioned whether the fight-or-flight model applies equally well to both males and females. They note that in most species females have more responsibility for the care of young offspring than males do. Using an evolutionary perspective, they argue that this disparity may make fighting and fleeing less adaptive for females, as both responses may endanger offspring and thus reduce the likelihood of an animal passing on its genes. Taylor et al. (2000) maintain that evolutionary processes have fostered more of a "tend and befriend" response in females. According to this analysis, in reacting to stress, females allocate more effort to the care of offspring and to seeking help and support. More research is needed to evaluate this provocative analysis. Although gender differences may exist in behavioral responses to stress, Taylor and her colleagues are quick to note that the "basic neuroendocrine core of stress responses" is largely the same for males and females.

The General Adaptation Syndrome 11g

The concept of stress was identified and named by Hans Selye (1936, 1956, 1982). Selye was born in Vienna but spent his entire professional career at McGill University in Montreal. Beginning in the 1930s, Selye exposed laboratory animals to a diverse array of both physical and psychological stressors (heat, cold, pain, mild shock, restraint, and so on). The resulting patterns of physiological arousal seen in the animals were largely the same, regardless of the type of stress. Thus, Selye concluded that stress reactions are *nonspecific.* In other words, he maintained that the reactions do not vary according to the specific type of stress encountered. Initially, Selye wasn't sure what to call this nonspecific response to a variety of noxious agents. In the 1940s he decided to call it *stress,* and the word has been part of our vocabulary ever since (Russell, 2007).

Selye (1956, 1974) formulated an influential theory of stress reactions called the general adaptation syndrome. **The *general adaptation syndrome* is a model of the body's stress response, consisting of three stages: alarm, resistance, and exhaustion.** In the first stage of the general adaptation syndrome, an *alarm reaction* occurs when an organism first recognizes the existence of a threat. Physiological arousal occurs as the body musters its resources to combat the challenge. Selye's alarm reaction is essentially the fight-or-flight response originally described by Cannon.

However, Selye took his investigation of stress a few steps further by exposing laboratory animals to *prolonged* stress, similar to the chronic stress often endured by humans. As stress continues, the organism may progress to the second phase of the general adaptation syndrome, the *stage of resistance.* During this phase, physiological changes stabilize as coping efforts get under way. Typically, physiological arousal continues to be higher than normal, al-

DILBERT
though it may level off somewhat as the organism becomes accustomed to the threat.

If the stress continues over a substantial period of time, the organism may enter the third stage, the *stage of exhaustion.* According to Selye, the body's resources for fighting stress are limited. If the stress can't be overcome, the body's resources may be depleted. Eventually, he thought the organism would experience hormonal exhaustion, although we now know that the crux of the problem is that chronic overactivation of the stress response can have damaging physiological effects on a variety of organ systems (Sapolsky, 2007). These harmful physiological effects can lead to what Selye called "diseases of adaptation."

Brain-Body Pathways

Even in cases of moderate stress, you may notice that your heart has started beating faster, you've begun to breathe harder, and you're perspiring more than usual. How does all this bodily activity (and much more) happen? It appears that there are two major pathways along which the brain sends signals to the endocrine system in response to stress (Clow, 2001; Dallman, Bhatnagar, & Viau, 2007; Tsigos, Kyrou, & Chrousos, 2005). As we noted in Chapter 3, the *endocrine system* consists of glands located at various sites in the body that secrete chemicals called hormones. The *hypothalamus* is the brain structure that appears to initiate action along these two pathways.

The first pathway (see **Figure 13.6**) is routed through the autonomic nervous system. In response to stress, your hypothalamus activates the sympathetic division of the ANS. A key part of this activation involves stimulating the central part of the adrenal glands (the adrenal medulla) to release large amounts of *catecholamines* into the bloodstream. These hormones radiate throughout your body, producing the physiological changes seen in the fight-or-flight response. The net result of catecholamine elevation is that your body is mobilized for action (Lundberg, 2007). Heart rate and blood flow increase,

and more blood is pumped to your brain and muscles. Respiration and oxygen consumption speed up, which facilitates alertness. Digestive processes are inhibited to conserve your energy. The pupils of your eyes dilate, increasing visual sensitivity.

The second pathway involves more direct communication between the brain and the endocrine system (see **Figure 13.6**). The hypothalamus sends signals to the so-called master gland of the endocrine system, the pituitary. In turn, the pituitary se-

Figure 13.6
Brain-body pathways in stress. In times of stress, the brain sends signals along two pathways. The pathway through the autonomic nervous system controls the release of catecholamine hormones that help mobilize the body for action. The pathway through the pituitary gland and the endocrine system controls the release of corticosteroid hormones that increase energy and ward off tissue inflammation.

cretes a hormone (ACTH) that stimulates the outer part of the adrenal glands (the adrenal cortex) to release another important set of hormones—*corticosteroids*. These hormones stimulate the release of chemicals that help increase your energy and help inhibit tissue inflammation in case of injury (Miller, Chen, & Zhou, 2007; Munck, 2007).

An important new finding in research on stress and the brain is that stress can interfere with neurogenesis (Mirescu & Gould, 2006). As you may recall from Chapter 3, scientists have recently discovered that the adult brain is capable of **neurogenesis—the formation of new neurons,** primarily in key areas in the hippocampus. Neurogenesis appears to enhance learning and memory (see Chapter 7) and in Chapter 14 we will discuss evidence that suppressed neurogenesis may be a key cause of depression (Dranovsky & Hen, 2006). Thus, the capacity of stress to hinder neurogenesis may have important ramifications, which are currently the subject of intense research (Tanapat & Gould, 2006).

Behavioral Responses   11g

Although people respond to stress at several levels, it's clear that *behavior* is the crucial dimension of their reactions. Most behavioral responses to stress involve coping. **Coping refers to active efforts to master, reduce, or tolerate the demands created by stress.** Notice that this definition is neutral as to whether coping efforts are healthful or maladaptive. The popular use of the term often implies that coping is inherently healthful. When people say that someone "coped with her problems," the implication is that she handled them effectively.

In reality, however, coping responses may be adaptive or maladaptive (Folkman & Moskowitz, 2004; Kleinke, 2007). For example, if you were flunking a history course at midterm, you might cope with this stress by (1) increasing your study efforts, (2) seeking help from a tutor, (3) blaming your professor, or (4) giving up on the class without really trying. Clearly, the first two of these coping responses would be more adaptive than the last two. Thus, they may help or they may hurt, but coping tactics are the key determinant of whether stress leads to distress (Carver, 2007).

People cope with stress in an endless variety of ways (Folkman & Moskowitz, 2004). One review of coping research examined 100 scales intended to assess coping and found about 400 specific coping strategies (Skinner et al., 2003). Thus, in dealing with stress, people choose their coping strategies from a large and diverse menu of options.

That said, most individuals exhibit certain styles of coping that are fairly consistent across situations

(Carver & Scheier, 1994; Jang et al., 2007). Of course, an individual's coping strategies are also influenced by situational demands, and Cheng (2001, 2003) has argued that flexibility in coping is more desirable than consistently depending on the same strategy. According to Cheng and Cheung (2005), people who exhibit flexible coping differentiate among stressful events in terms of controllability and probable impact, allowing them to make better-informed decisions about how to handle stressful challenges.

Given the immense variety in coping strategies, we can only highlight a few of the more common patterns. In this section we'll focus most of our attention on styles of coping that tend to be less than ideal. We'll discuss a variety of more healthful coping strategies in the Personal Application on stress management.

Giving Up and Blaming Oneself   11g

When confronted with stress, people sometimes simply give up and withdraw from the battle. Some people routinely respond to stress with fatalism and resignation, passively accepting setbacks that might be dealt with effectively. This syndrome is referred to as *learned helplessness* (Seligman, 1974, 1992). **Learned helplessness is passive behavior produced by exposure to unavoidable aversive events.** Learned helplessness seems to occur when individuals come to believe that events are beyond their control. As you might guess, giving up generally has not been highly regarded as a method of coping. Consistent with this view, many studies suggest that learned helplessness can contribute to depression (Isaacowitz & Seligman, 2007).

Although giving up is clearly less than optimal in many contexts, new research suggests that when people struggle to pursue goals that turn out to be unattainable, it makes sense for them to cut their losses and disengage from the goal (Wrosch & Scheier, 2003). Recent studies have shown that people who are better able to disengage from unattainable goals report better health and exhibit lower levels of a key stress hormone (Wrosch et al., 2007). They also manifest lower levels of a protein marker associated with inflammation, which is thought to underlie many disease processes (Miller & Wrosch, 2007). Given the way people in our competitive culture tend to disparage the concept of "giving up," the authors note that it might be better to characterize this coping tactic as "goal adjustment."

Blaming oneself is another common response when people are confronted by stressful difficulties. The tendency to become highly self-critical in response to stress has been noted by a number of in-

fluential theorists. Albert Ellis (1973, 1987) calls this phenomenon "catastrophic thinking." According to Ellis, catastrophic thinking causes, aggravates, and perpetuates emotional reactions to stress that are often problematic (see the Personal Application for this chapter). In a similar vein, Aaron Beck (1976, 1987) argues that negative self-talk can contribute to the development of depressive disorders (see Chapter 15). Although there is something to be said for recognizing one's weaknesses and taking responsibility for one's failures, Ellis and Beck agree that excessive self-blame can be unhealthy.

Striking Out at Others   11g

People often respond to stressful events by striking out at others with aggressive behavior. *Aggression* is any behavior that is intended to hurt someone, either physically or verbally. Many years ago, a team of psychologists (Dollard et al., 1939) proposed the *frustration-aggression hypothesis,* which held that aggression is always caused by frustration. Decades of research have supported this idea of a causal link between frustration and aggression (Berkowitz, 1989). However, this research has also shown that there isn't an inevitable, one-to-one correspondence between frustration and aggression.

Frequently people lash out aggressively at others who had nothing to do with their frustration, apparently because they can't vent their anger at the real source. For example, you'll probably suppress your anger rather than lash out verbally at your boss or at a police officer who's giving you a speeding ticket. Twenty minutes later, however, you might be verbally brutal to a sales clerk. As we discussed in Chapter 12, this diversion of anger to a substitute target was noticed long ago by Sigmund Freud, who called it *displacement.* Unfortunately, research suggests that when people are provoked, displaced aggression is a common response (Marcus-Newhall et al., 2000).

Freud theorized that behaving aggressively could get pent-up emotion out of one's system and thus be adaptive. He coined the term *catharsis* to refer to this release of emotional tension. The Freudian notion that it is a good idea to vent anger has become widely disseminated and accepted in modern society. Books, magazines, and self-appointed experts routinely advise that it is healthy to "blow off steam" and thereby release and reduce anger. However, experimental research generally has *not* supported the catharsis hypothesis. Indeed, *most studies find just the opposite: Behaving in an aggressive manner tends to fuel more anger and aggression* (Bushman, 2002; Bushman, Baumeister, & Stack, 1999).

Indulging Oneself   11g

Stress sometimes leads to reduced impulse control, or *self-indulgence* (Tice, Bratslavsky, & Baumeister, 2001). When troubled by stress, many people engage in excessive consumption—unwise patterns of eating, drinking, smoking, using drugs, spending money, and so forth. For example, I have a friend who copes with stress by making a beeline for the nearest shopping mall to indulge in a spending spree. It appears that my friend is not unusual. It makes sense that when things are going poorly in one area of their lives, people may try to compensate by pursuing substitute forms of

Lashing out at others with verbal aggression tends to be an ineffective coping tactic that often backfires, creating additional stress.
Albert Ellis

"People largely disturb themselves by thinking in a self-defeating, illogical, and unrealistic manner."

CATHY

YOU WENT OUT AND GOT DRUNK BECAUSE YOU WERE JEALOUS? THAT WAS STUPID.

HOW IS THAT ANY MORE STUPID THAN YOU EATING WHEN YOU'RE JEALOUS?

IRVING, I EAT WHEN I'M **DEPRESSED**, I BUY **SHOES** WHEN I'M JEALOUS. I BREAK THE TELEPHONE WHEN I'M ANGRY...

I MANGLE MY FINGERNAILS WHEN I'M LONELY...I THROW THINGS ALL OVER THE HOUSE WHEN I'M HURT...AND I WASTE MONEY ON MAKE-UP WHEN I'M FRUSTRATED.

MEN JUST DON'T KNOW HOW TO COPE.

satisfaction. After all, self-indulgent responses tend to be relatively easy to execute and highly pleasurable. Thus, it's not surprising that studies have linked stress to increases in eating (Barker, Williams, & Galambos, 2006), smoking (Kassel, Stroud, & Paronis, 2003), and consumption of alcohol and drugs (Goeders, 2004; Spada & Wells, 2006).

A new manifestation of this coping strategy that has attracted much attention recently is the tendency to immerse oneself in the online world of the Internet. Kimberly Young (1996, 1998) has described a syndrome called *Internet addiction,* **which consists of spending an inordinate amount of time on the Internet and inability to control online use.** People who exhibit this syndrome tend to feel anxious, depressed, or empty when they are not online (Kandell, 1998). Their Internet use is so excessive, it begins to interfere with their functioning at work, at school, or at home, which leads them to start concealing the extent of their dependence on the Internet. It is difficult to estimate the prevalence of Internet addiction, but the syndrome does *not* appear to be rare (Greenfield, 1999; Morahan-Martin & Schumacher, 2000). Although there is active debate about the wisdom of characterizing excessive Internet surfing as an *addiction* (Goldsmith & Shapira, 2006; Griffiths, 1999), it is clear that this new coping strategy is creating very real problems for at least a small portion of Internet users (Morahan-Martin, 2007).

Defensive Coping   10a, 11g

Many people exhibit consistent styles of defensive coping in response to stress (Vaillant, 1994). We noted in the previous chapter that Sigmund Freud originally developed the concept of the *defense mechanism.* Though rooted in the psychoanalytic tradition,

this concept has gained widespread acceptance from psychologists of most persuasions (Cramer, 2000). Building on Freud's initial insights, modern psychologists have broadened the scope of the concept and added to Freud's list of defense mechanisms.

Defense mechanisms **are largely unconscious reactions that protect a person from unpleasant emotions such as anxiety and guilt.** Many specific defense mechanisms have been identified. For example, Laughlin (1979) lists 49 different defenses. We described 7 common defense mechanisms in our discussion of Freud's theory in the previous chapter. Table 13.2 introduces another 5 defenses that people use with some regularity: denial, fantasy, intellectualization, undoing, and overcompensation. Although widely discussed in the popular press, defense mechanisms are often misunderstood. To clear up some of the misconceptions, we'll use a question/answer format to elaborate on the nature of defense mechanisms.

What exactly do defense mechanisms defend against? Above all else, defense mechanisms shield the individual from the emotional discomfort that's so often elicited by stress. Their main purpose is to ward off unwelcome emotions or to reduce their intensity. Foremost among the emotions guarded against are anxiety, anger, guilt, and dejection.

How do they work? Through *self-deception.* Defense mechanisms accomplish their goals by distorting reality so that it doesn't appear so threatening. For example, suppose you're not doing well in school and you're in danger of flunking out. Initially you might use *denial* to block awareness of the possibility that you could flunk. This defense might temporarily fend off feelings of anxiety. If it becomes difficult to deny the obvious, you could resort to *fantasy.* You might daydream about how you'll sal-

Table 13.2 Additional Defense Mechanisms

Mechanism	Description	Example
Denial of reality	Protecting oneself from unpleasant reality by refusing to perceive or face it	A smoker concludes that the evidence linking cigarette use to health problems is scientifically worthless
Fantasy	Gratifying frustrated desires by imaginary achievements	A socially inept and inhibited young man imagines himself chosen by a group of women to provide them with sexual satisfaction
Intellectualization (isolation)	Cutting off emotion from hurtful situations or separating incompatible attitudes so that they appear unrelated	A prisoner on death row awaiting execution resists appeal on his behalf and coldly insists that the letter of the law be followed
Undoing	Atoning for or trying to magically dispel unacceptable desires or acts	A teenager who feels guilty about masturbation ritually touches door knobs a prescribed number of times following each occurrence of the act
Overcompensation	Covering up felt weakness by emphasizing some desirable characteristics, or making up for frustration in one area by overgratification in another	A dangerously overweight woman goes on eating binges when she feels neglected by her husband

Note: See Table 12.1 for another list of defense mechanisms.

vage adequate grades by getting spectacular scores on the upcoming final exams, when the objective fact is that you're hopelessly behind in your studies. Thus, defense mechanisms work their magic by bending reality in self-serving ways.

Are they conscious or unconscious? Both. Freudian theory originally assumed that defenses operate entirely at an unconscious level. However, the concept of the defense mechanism has been broadened by other theorists to include maneuvers that people may be aware of. Thus, defense mechanisms may operate at varying levels of awareness, although they're largely unconscious (Cramer, 2001; Erdelyi, 2001).

Are they healthy? This is a complicated question. More often than not, the answer is "no." Generally, defensive coping is less than optimal. Avoidance strategies and wishful thinking rarely provide genuine solutions to personal problems (Bolger, 1990; Holahan & Moos, 1990). Although defensive behavior tends to be relatively unhealthful, Shelley Taylor and Jonathon Brown (1988, 1994) have reviewed several lines of evidence suggesting that "positive illusions" may be adaptive for mental health and well-being. First, they note that "normal" people tend to have overly favorable self-images. In contrast, depressed subjects exhibit less favorable—but more realistic—self-concepts. Second, normal subjects overestimate the degree to which they control chance events. In comparison, depressed subjects are less prone to this illusion of control. Third, normal individuals are more likely than depressed subjects to display unrealistic optimism in making projections about the fu-

ture. A variety of studies have provided support for the hypothesis that positive illusions can promote well-being (Reed et al., 1999; Taylor et al., 2003).

As you might guess, a variety of critics have expressed skepticism about the idea that illusions are adaptive (Asendorpf & Ostendorf, 1998; Colvin, Block, & Funder, 1995). Perhaps the best analysis of the issue comes from Roy Baumeister (1989), who theorizes that it's all a matter of degree and that there is an "optimal margin of illusion." According to Baumeister, extreme distortions of reality are maladaptive, but small illusions are often beneficial.

Constructive Coping   11g

Our discussion thus far has focused on coping strategies that usually are less than ideal. Of course, people also exhibit many healthful strategies for dealing with stress. The term *constructive coping* **refers to relatively healthful efforts that people make to deal with stressful events.** No strategy of coping can *guarantee* a successful outcome. The coping strategies that are likely to be effective will vary depending on the exact nature of the situation, and even the healthiest coping responses may turn out to be ineffective in some circumstances (Folkman & Moskowitz, 2004). Thus, the concept of constructive coping is simply meant to connote a healthful, positive approach, without promising success.

What makes certain coping strategies constructive? Frankly, it's a gray area in which psychologists' opinions vary to some extent. Nonetheless, a consensus

Shelley Taylor

"Rather than perceiving themselves, the world, and the future accurately, most people regard themselves, their circumstances, and the future as considerably more positive than is objectively likely.... These illusions are not merely characteristic of human thought; they appear actually to be adaptive, promoting rather than undermining good mental health."

concept check 13.3

Identifying More Defense Mechanisms

In the last chapter you checked your understanding of several defense mechanisms by identifying instances of them in a story. In this chapter, you've learned about five additional defense mechanisms that are sometimes used as ways of coping with stress (see **Table 13.2**). Check your understanding of these defense mechanisms by identifying them in the story below. Each example of a defense mechanism is underlined, with a number beneath it. Write the name of the defense mechanism exemplified in each case in the numbered spaces after the story. The answers are in Appendix A.

The guys at work have been trying to break it to me gently that they think my job's on the line because I've missed work too many days this year. I don't know how they came up with that idea; I've got nothing to worry about. Besides, every day I missed, I always did a lot of cleaning up and other chores around here. One of these days the boss will finally recognize how really valuable I am to the company, and I'll be getting a big promotion. Anyway, since the guys have been dropping these hints about my not missing any more days, I've been trying really hard to make a good impression by saying "Hi" to everyone I see, especially the boss, and telling jokes. You know, it's really pretty interesting to observe how all these relationships unfold between guys who work together and the people who manage them.

3. _____

about the nature of constructive coping has emerged from the sizable literature on stress management. Key themes in this literature include the following:

1. Constructive coping involves confronting problems directly. It is task relevant and action oriented. It entails a conscious effort to rationally evaluate your options so that you can try to solve your problems.

2. Constructive coping is based on reasonably realistic appraisals of your stress and coping resources. A little self-deception may sometimes be adaptive, but excessive self-deception and highly unrealistic negative thinking are not.

3. Constructive coping involves learning to recognize, and in some cases regulate, potentially disruptive emotional reactions to stress.

4. Constructive coping includes making efforts to ensure that your body is not especially vulnerable to the possibly damaging effects of stress.

These principles provide a rather general and abstract picture of constructive coping. We'll look at patterns of constructive coping in more detail in the Personal Application, which discusses various stress management strategies that people can use.

REVIEW of Key Points

13.5 Stress often triggers emotional reactions, such as anger, fear, and sadness. Fredrickson's broaden-and-build theory asserts that positive emotions broaden thinking and build coping resources. Evidence suggests that positive emotions foster enhanced immune responding and mental and physical health. Emotional arousal may interfere with coping. According to the inverted-U hypothesis, task performance improves with increased arousal up to a point and then declines. The optimal level of arousal on a task depends on the complexity of the task.

13.6 In the fight-or-flight response, the autonomic nervous system mobilizes the body for attack or fleeing. It may be less applicable to women than to men. Selye's general adaptation syndrome describes three stages of physiological reactions to stress: alarm, resistance, and exhaustion. Diseases of adaptation may appear during the stage of exhaustion. There are two major pathways along which the brain sends signals to the endocrine system in response to stress, leading to the release of catecholamines and corticosteroids.

13.7 The behavioral response to stress takes the form of coping. Giving up is not a highly regarded approach to coping, but studies suggest that people who are able to disengage from unattainable goals exhibit better health. Aggression tends to fuel more anger and increase rather than decrease stress. Self-indulgence is another coping pattern that tends to be of limited value.

13.8 Defensive coping is quite common. Defense mechanisms protect against emotional distress through self-deception. Several lines of evidence suggest that positive illusions may be healthful, but there is some debate about the matter. Relatively healthful coping tactics are called constructive coping. Constructive coping is action-oriented and based on realistic appraisals of stress.

The Effects of Stress on Psychological Functioning

Key Learning Goals

13.9 Analyze the effects of stress on task performance and the nature of the burnout syndrome.

13.10 List some psychological problems that may be stress related, and explain how stress may have positive effects.

People struggle with many stresses every day. Most stresses come and go without leaving any enduring imprint. However, when stress is severe or when many stressful demands pile up, one's psychological functioning may be affected.

Research on the effects of stress has focused mainly on negative outcomes, so our coverage is slanted in that direction. However, it's important to emphasize that stress is not inherently bad. You would probably suffocate from boredom if you lived a stress-free existence. Stress makes life challenging and interesting. Along the way, though, stress can be harrowing, sometimes leading to impairments in performance, to burnout, and to other problems.

Impaired Task Performance

Stress often takes its toll on the ability to perform effectively on a task at hand. For instance, Roy Baumeis-ter's work shows how pressure can interfere with performance. Baumeister's (1984) theory assumes that pressure to perform often makes people self-conscious and that this elevated self-consciousness disrupts their attention. He found support for his theory in a series of laboratory experiments in which he manipulated the pressure to perform on simple perceptual-motor tasks and found that many people tend to "choke" under pressure (Butler & Baumeister, 1998; Wallace, Baumeister, & Vohs, 2005). Pressure-induced performance decrements have also been found in studies of mathematical problem-solving and simple sports tasks (Beilock et al., 2002, 2004).

Other research suggests that Baumeister is on the right track in looking to *attention* to explain how stress impairs task performance. In a study of stress and decision making, Keinan (1987) found that stress disrupted two out of the three aspects of attention measured in the study. Stress increased

subjects' tendency (1) to jump to a conclusion too quickly without considering all their options and (2) to do an unsystematic, poorly organized review of their available options. In a more recent study, Keinan and colleagues (1999) found that stress impaired performance on cognitive tasks. The results suggested that stress makes it harder for people to suppress competing thoughts. Research also suggests that stress can have detrimental effects on certain memory functions (Neupert et al., 2006; Shors, 2004), especially working memory (Beilock & Carr, 2005).

Burnout

Burnout is an overused buzzword that means different things to different people. Nonetheless, a few researchers have described burnout in a systematic way that has facilitated scientific study of the syndrome (Maslach, 2003; Maslach & Leiter, 2007). *Burnout involves physical and emotional exhaustion, cynicism, and a lowered sense of self-efficacy that can be brought on gradually by chronic work-related stress.* Exhaustion, which is central to burnout, includes chronic fatigue, weakness, and low energy. Cynicism is manifested in highly negative attitudes toward oneself, one's work, and life in general. Reduced self-efficacy involves declining feelings of competence at work that give way to feelings of hopelessness and helplessness.

What causes burnout? Factors in the workplace that appear to promote burnout include work overload, struggling with interpersonal conflicts at work, lack of control over work responsibilities and outcomes, and inadequate recognition for one's work (Maslach & Leiter, 2005; see **Figure 13.7**). As you might expect, burnout is associated with increased absenteeism and reduced productivity at work, as well as increased vulnerability to a variety of health problems (Maslach & Leiter, 2000). Burnout is a potential problem in a wide variety of occupations (Lee & Ashforth, 1996).

Psychological Problems and Disorders

On the basis of clinical impressions, psychologists have long suspected that chronic stress might contribute to many types of psychological problems and mental disorders. Since the late 1960s, advances in the measurement of stress have allowed researchers to verify these suspicions in empirical studies. When it comes to common psychological problems,

Antecedents of burnout

- Work overload
- Lack of social support
- Lack of control, autonomy
- Inadequate recognition, rewards

Components of burnout

- Exhaustion
- Cynicism
- Lowered self-efficacy

Consequences of burnout

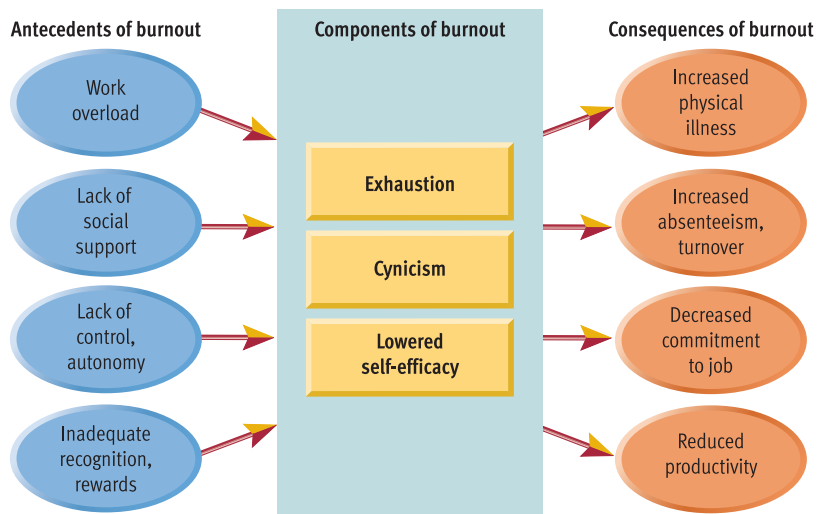
- Increased physical illness
- Increased absenteeism, turnover
- Decreased commitment to job
- Reduced productivity


Figure 13.7

The antecedents, components, and consequences of burnout. Christina Maslach and Michael Leiter have developed a systematic model of burnout that specifies the antecedents, components, and consequences of this syndrome. The antecedents on the left in the diagram are the stressful features of the work environment that cause burnout. The syndrome itself consists of the three components shown in the center of the diagram. Some of the unfortunate results of burnout are listed on the right. (Based on Leiter & Maslach, 2001)

studies indicate that stress may contribute to poor academic performance (Akgun & Ciarrochi, 2003), insomnia and other sleep disturbances (Bernert et al., 2007; Kim & Dimsdale, 2007), sexual difficulties (Bodenmann et al., 2006), alcohol abuse (Sayette, 2007), and drug abuse (Goeders, 2004).

Above and beyond these everyday problems, research reveals that stress often contributes to the onset of full-fledged psychological disorders, including depression (Feliciano & Arean, 2007), schizophrenia (Walker, Mittal, & Tessner, 2008), and

Major disasters are just one of about a half-dozen types of calamitous events that can lead to posttraumatic stress disorder.

© Associated Press,/AP Images

anxiety disorders (Beidel & Stipelman, 2007). In particular, stress plays a central role in the development of *posttraumatic stress disorder (PTSD),* which involves an enduring psychological disturbance attributable to the experience of a major traumatic event. We'll discuss these relations between stress and mental disorders in detail in Chapter 14. Of course, stress is only one of many factors that may contribute to psychological disorders. Nonetheless, it's sobering to realize that stress can have a dramatic impact on one's mental health.

Positive Effects

The effects of stress are not entirely negative. Recent years have brought increased interest in the positive aspects of the stress process, including favorable outcomes that follow in the wake of stress (Folkman & Moskowitz, 2000). To some extent, the new focus on the possible benefits of stress reflects a new emphasis on "positive psychology." As we noted in Chapters 1 and 10, some theorists have argued that the field of

psychology has historically devoted too much attention to pathology and suffering (Seligman & Csikszentmihalyi, 2000). The advocates of positive psychology argue for increased research on well-being, hope, courage, perseverance, tolerance, and other human strengths and virtues (Peterson & Seligman, 2004). One of these strengths is *resilience* in the face of stress.

Research on resilience suggests that stress can promote personal growth or self-improvement (Calhoun & Tedeschi, 2006, 2008). For example, studies of people grappling with major health problems show that the majority of respondents report they derived benefits from their adversity (Tennen & Affleck, 1999). Stressful events sometimes force people to develop new skills, reevaluate priorities, learn new insights, and acquire new strengths. In other words, the adaptation process initiated by stress may lead to personal changes that are for the better. Confronting and conquering a stressful challenge may lead to improvements in specific coping abilities and to an enhanced self-concept. Moreover, even if people do not conquer stressors, they may be able to learn from their mistakes. Thus, researchers have begun to explore the growth potential of stressful events (Helgeson, Reynolds, & Tomich, 2006; Park & Fenster, 2004).

The predominant view has been that a substantial majority of people who are exposed to traumatic stress tend to suffer severe effects, with resilience being unusual, perhaps even rare. However, George Bonanno (2005) and his colleagues (Bonanno et al., 2002, 2005), who have studied the long-term effects of traumatic stressful events such as bereavement and exposure to combat and terrorism, have found that resilience is seen in as many as 35% to 55% of people (see **Figure 13.8**). Admittedly, a great many people do experience lasting ill effects from traumatic stress, but resilience is not the rare exception it was once believed to be.

Figure 13.8

Patterns of response to traumatic stress. Bonanno (2005) and colleagues have conducted a number of studies in which they have tracked the adjustment of people after exposure to severe, traumatic stress, such as bereavement. They have identified four patterns of response. Some people experience *chronic disruption* and others show *delayed disruption* of normal functioning, both of which show no abatement after two years. Others show a pattern of *recovery,* wherein initially severe symptoms gradually taper off. Finally, a fourth group exhibits *resilience,* in which relatively modest initial symptoms diminish fairly quickly. The surprising finding in this research is that resilience is the most common of the four patterns, suggesting that resilience is not as rare as previously assumed.

REVIEW of Key Points

13.9 Several lines of research, including Baumeister's work on choking under pressure, suggest that stress can interfere with task performance. Burnout involves exhaustion, cynicism, and lowered self-efficacy as a result of chronic work-related stress.

13.10 Stress can contribute to a number of common problems, such as poor academic performance, insomnia, and sexual difficulties. Stress has also been related to the development of depression, schizophrenia, and anxiety disorders. Research on the effects of stress has concentrated on negative outcomes, but positive effects may also occur. Research on resilience suggests that stress can promote personal growth and improved coping.

The Effects of Stress on Physical Health

The idea that stress can contribute to physical ailments is not entirely new. Evidence that stress can cause physical illness began to accumulate back in the 1930s. By the 1950s, the concept of *psychosomatic disease* was widely accepted. **Psychosomatic diseases were genuine physical ailments that were thought to be caused in part by stress and other psychological factors.** The classic psychosomatic illnesses were high blood pressure, peptic ulcers, asthma, skin disorders such as eczema and hives, and migraine and tension headaches (Kaplan, 1989; Rogers, Fricchione, & Reich, 1999). Please note, these diseases were not regarded as *imagined* physical ailments. The term *psychosomatic* has often been misused to refer to physical ailments that are "all in one's head," but that is an entirely different syndrome (see Chapter 14). Rather, psychosomatic diseases were viewed as *authentic* organic maladies that were heavily stress-related.

Since the 1970s, the concept of psychosomatic disease has gradually fallen into disuse because research has shown that stress can contribute to the development of a diverse array of other diseases previously believed to be purely physiological in origin (Dimsdale et al., 2005; Dougall & Baum, 2001). Thus, it has become apparent that there is nothing unique about the psychosomatic diseases that requires a special category. In this section we'll look at the evidence on the apparent link between stress and physical illness, beginning with heart disease, which is far and away the leading cause of death in North America.

Personality, Hostility, and Heart Disease

Heart disease accounts for about 27% of the deaths in the United States every year. *Coronary heart disease* involves a reduction in blood flow in the coronary arteries, which supply the heart with blood. This type of heart disease accounts for about 90% of heart-related deaths.

Atherosclerosis is the principal cause of coronary heart disease (Chrousos & Kaltsas, 2007). This condition is characterized by a gradual narrowing of the coronary arteries. A buildup of fatty deposits and other debris on the inner walls of the arteries is the usual cause of this narrowing. Atherosclerosis progresses slowly over a period of years. However, when a narrowed coronary artery is blocked completely (by a blood clot, for instance), the abrupt interruption of blood flow can produce a heart attack. Atherosclerosis is more prevalent in men than women and tends to increase with age. Other established risk factors for atherosclerosis include smoking, lack of exercise, high cholesterol levels, and high blood pressure (Rippe, Angelopoulos, & Zukley, 2007). Contrary to public perception, cardiovascular diseases kill women just as much as men, but these diseases tend to emerge in women about 10 years later than in men (Stoney, 2003).

Recently, attention has shifted to the possibility that inflammation may contribute to atherosclerosis and elevated coronary risk (Miller & Blackwell, 2006). Evidence is mounting that inflammation plays a key role in the initiation and progression of atherosclerosis, as well as in the acute complications that trigger heart attacks (Nabi et al., 2008). Fortunately, researchers have found a marker for inflammation—levels of C-reactive protein (CRP) in the blood—that may help physicians estimate individuals' coronary risk more accurately than was previously possible (Kop & Weinstein, 2007; Ridker et al., 2005). **Figure 13.9** on the next page shows how combined levels of CRP and cholesterol appear to be related to coronary risk.

Research on the relationship between *psychological* factors and heart attacks began in the 1960s and 1970s, when a pair of cardiologists, Meyer Friedman and Ray Rosenman (1974), discovered an apparent connection between coronary risk and a syndrome they called the *Type A personality,* which involves self-imposed stress and intense reactions to stress (Shaw & Dimsdale, 2007). **The *Type A personality* includes three elements: (1) a strong competitive orientation, (2) impatience and time urgency, and (3) anger and hostility.** Type A's are ambitious, hard-driving perfectionists who are exceedingly time-conscious. They routinely try to do several things at once. They fidget frantically over the briefest delays. Often they are highly competitive, achievement-oriented workaholics who drive themselves with many deadlines. They are easily irritated and are quick to anger. In contrast, **the *Type B personality* is marked by relatively relaxed, patient, easygoing, amicable behavior.** Type B's are less hurried, less competitive, and less easily angered than Type A's.

Key Learning Goals

13.11 Review the evidence linking personality factors to coronary heart disease.

13.12 Outline the evidence linking emotional reactions and depression to heart disease.

13.13 Discuss how stress affects immune functioning, and assess the link between stress and illness.
Figure 13.9

The relationship of cholesterol and inflammation to coronary risk. Levels of C-reactive protein (CRP) in the blood appear to be a useful index of the inflammation that contributes to atherosclerosis (Ridker, 2001). This graph shows how increasing CRP levels and increasing cholesterol levels combine to elevate cardiovascular risk (for a heart attack or stroke). The relative risks shown are for successive quintiles on each measure (each quintile represents one-fifth of the sample, ordered from those who scored lowest to those who scored highest). The relative risks are in relation to those who fall in the lowest quintile on both measures.

Decades of research uncovered a tantalizingly modest correlation between Type A behavior and increased coronary risk. More often than not, studies found an association between Type A personality and an elevated incidence of heart disease, but the findings were not as strong or as consistent as expected (Baker, Suchday, & Krantz, 2007; Myrtek, 2007). However, more recently, researchers have found a stronger link between personality and coronary risk by focusing on a specific component of the Type A personality—*anger and hostility* (Boyle, Jackson, & Suarez, 2007; Powell & Williams, 2007). For example, in one study of almost 13,000 men and women who had no prior history of heart disease (Williams et al., 2000), investigators found an elevated incidence of heart attacks among participants who exhibited an angry temperament. The participants, who were followed for a median period of 4.5 years, were classified as being low (37.1%), moderate (55.2%), or high (7.7%) in anger. Among participants with normal blood pressure, the high-anger subjects experienced almost three times as many coronary events as the low-anger subjects (see **Figure 13.10**). Thus, anger/hostility appears to be the key toxic element in the Type A syndrome.

Emotional Reactions, Depression, and Heart Disease

Although work on personality risk factors has dominated research on how psychological functioning contributes to heart disease, recent studies suggest
Figure 13.10

Anger and coronary risk. Working with a large sample of healthy men and women who were followed for a median of 4.5 years, Williams et al. (2000) found an association between anger and the likelihood of a coronary event. Among subjects who manifested normal blood pressure at the beginning of the study, a moderate anger level was associated with a 36% increase in coronary attacks and a high level of anger nearly tripled participants' risk for coronary disease. (Based on data in Williams et al., 2000)

that emotional reactions may also be critical. *One line of research has supported the hypothesis that transient mental stress and the resulting emotions that people experience can tax the heart.* Based on anecdotal

evidence, cardiologists and laypersons have long voiced suspicions that strong emotional reactions might trigger heart attacks in individuals with coronary disease, but it has been difficult to document this connection. However, advances in cardiac monitoring have facilitated investigation of the issue.

As suspected, laboratory experiments have shown that brief periods of mental stress can trigger acute symptoms of heart disease (Baker, Suchday, & Krantz, 2007). Overall, the evidence suggests that mental stress can elicit cardiac symptoms in about 30%–70% of patients with coronary disease (Kop, Gottdiener, & Krantz, 2001). Moreover, research indicates that these patients have a higher risk for heart attack than the cardiology patients who do not exhibit symptoms in response to mental stress (Krantz et al., 2000). A recent study also demonstrated that mental stress can trigger temporary increases in the inflammation that is thought to contribute to cardiovascular risk (Kop et al., 2008). Subjects asked to perform stressful tasks in the laboratory showed elevated CRP levels, and these reactions were stronger in participants who had a history of coronary disease.

Another line of research has recently implicated depression as a risk factor for heart disease (Goldston & Baillie, 2008). *Depressive disorders,* which are characterized by persistent feelings of sadness and despair, are a fairly common form of mental illness (see Chapter 14). Elevated rates of depression have been found among patients suffering from heart disease, but most experts used to explain this correlation by asserting that being diagnosed with heart disease makes people depressed. Recent evidence, however, suggests that the causal relations may be just the opposite—*that the emotional dysfunction of depression may cause heart disease* (Frasure-Smith & Lesperance, 2005; Thomas, Kalaria, & O'Brien, 2004). This issue brings us to our Featured Study for this chapter, which examined the relationship between depression and cardiac health.

FEATURED STUDY

Is Depression a Risk Factor for Heart Disease?

In the 1990s investigators began to suspect that depression might increase vulnerability to heart disease. A correlation between depression and coronary risk was reported in several studies, but given the profound importance of this issue, additional studies have been needed to replicate the finding in different types of samples and to get a more precise reading on the *degree* to which depression elevates coronary risk. Also, previous studies yielded conflicting results about whether depression elevates cardiac risk for healthy individuals or only among people who already have heart disease. Thus, the present study examined the impact of depression on cardiac mortality in people with and without preexisting coronary disease.

Method

Participants. The sample was made up of 2847 men and women between the ages of 55 and 85 who were participating in an ongoing study of aging based in Amsterdam. The subjects were a randomly selected sample of older persons drawn from 11 municipalities in the Netherlands. The mean age of the participants was 70.5, and 52% were female.

Procedure and measures. The study used a longitudinal design (see Chapter 11), which entailed following the participants' health and mortality over a period of four years. Subjects were carefully screened for the existence of cardiac disease at the beginning of the study. Depressed subjects were identified through a two-step process. First, all the participants completed a widely used 20-item self-report measure of depression. Those who scored above a standard cutoff on this scale were evaluated four weeks later with a diagnostic interview. Those who met the criteria for a diagnosis of depressive disorder (based on the interview) were categorized as suffering from *major depression*. The remaining subjects who had scored above the cutoff on the screening scale but who did not meet the criteria for a full-fledged depressive disorder, were categorized as suffering from *minor depression*. The key dependent variable at the end of the study was the cardiac mortality rate among the subjects, which was based on tracking death certificates in the 11 municipalities where the participants resided.

Results

At the beginning of the study, 450 of the 2847 participants were found to have cardiac disease. Among these subjects, the cardiac mortality rate was elevated for those who had exhibited either minor or major depression (see **Figure 13.11a** on the next page). Similar trends were observed among the remaining 2397 subjects who were free of cardiac disease when the study was initiated (see **Figure 13.11b** on the next page). The risk trends for both groups remained largely the same even after statistical adjustments were made to control for confounding variables, such as age, sex, weight, and smoking history.

Discussion

The increased cardiac mortality rate associated with depression was fairly similar in subjects with and without preexisting cardiac disease. For both groups, major depression roughly tripled subjects' risk of cardiac death. The findings for subjects without preexisting cardiac disease were especially important. Given that these subjects' depressive disorders preceded their cardiac disease, one cannot argue that their heart disease caused their depression. It is far

(a) Participants with preexisting heart disease

(b) Participants without preexisting heart disease

more likely that depression somehow contributed to the emergence of cardiac disease in these subjects.

Comment

This study is representative of a rich research tradition in health psychology in which various psychological factors (depression in this case) are examined in relation to health outcomes. These studies are crucial to our understanding of the determinants of wellness and disease. They illustrate the importance of correlational research, since predictors of disease generally cannot be studied using the experimental method.

The tripled cardiac risk observed in our Featured Study was partly a function of the older age group (over age 55) that was studied. Overall, when broader age ranges are examined, other studies have found that depression roughly doubles one's chances of developing heart disease (Lett et al., 2004; Herbst et al., 2007). Moreover, as suggested by the Featured Study, depression also appears to influence how heart disease progresses, as it is associated with a worse prognosis among cardiology patients (Glassman et al., 2003). Although the new emphasis is on how depression contributes to heart disease, experts caution that the relationship between the two conditions is surely bidirectional and that heart disease also increases vulnerability to depression (Sayers, 2004).

Stress, Other Diseases, and Immune Functioning

The development of questionnaires to measure life stress has allowed researchers to look for correlations between stress and a variety of diseases. These researchers have uncovered many connections between stress and illness. For example, Zautra and Smith (2001) found an association between life stress and the course of rheumatoid arthritis. Other studies have connected stress to the development of diabetes (Landel-Graham, Yount, & Rudnicki, 2003), herpes (Padgett & Sheridan, 2000), fibromyalgia (Wood, 2007), and flare-ups of irritable bowel syndrome (Blanchard & Keefer, 2003).

These are just a handful of representative examples of studies relating stress to physical diseases. Table 13.3 provides a longer list of health problems that have been linked to stress. Many of these stress-illness connections are based on tentative or inconsistent findings, but the sheer length and diversity of the list is remarkable. Why should stress increase the risk for so many kinds of illness? A partial answer may lie in the immune system.

The apparent link between stress and many types of illness raises the possibility that stress may undermine immune functioning. **The *immune response* is the body's defensive reaction to invasion by bacteria, viral agents, or other foreign substances.** The immune response works to protect the body from many forms of disease. Immune reactions are multifaceted, but they depend heavily on actions initiated by specialized white blood cells, called *lymphocytes*.

A wealth of studies indicate that experimentally induced stress can impair immune functioning *in animals* (Ader, 2001; Rose, 2007). That is, stressors such as crowding, shock, food restriction, and restraint reduce various aspects of immune reactivity in laboratory animals (Prolo & Chiappelli, 2007).

Studies by Janice Kiecolt-Glaser and her colleagues have related stress to suppressed immune activity *in humans* (Kiecolt-Glaser & Glaser, 1995). In one study,

Table 13.3 Health Problems That May Be Linked to Stress

Health Problem	Representative Evidence

Vaginal infections	Williams & Deffenbacher (1983)

medical students provided researchers with blood samples so that their immune response could be assessed (Kiecolt-Glaser et al., 1984). The students provided the baseline sample a month before final exams and contributed the "high-stress" sample on the first day of their finals. The subjects also responded to the SRRS as a measure of recent stress. Reduced levels of immune activity were found during the extremely stressful finals week. Reduced immune activity was also correlated with higher scores on the SRRS. In another study, investigators exposed quarantined volunteers to respiratory viruses that cause the common cold and found that those under high stress were more likely to be infected by the viruses (Cohen, Tyrell, & Smith, 1993). In a thorough review of 30 years of research on stress and immunity, Segerstrom and Miller (2004) conclude that chronic stress can reduce both *cellular immune responses* (which attack intracellular pathogens, such as viruses) and *humoral immune responses* (which attack extracellular pathogens, such as bacteria).

Although research in recent decades has mainly focused on the link between stress and immunosuppression, recent studies have shown that there are other important connections between immune function and vulnerability to illness. When the immune system responds to infection or injury it may release proinflammatory cytokines, proteins that "orchestrate a number of the immune activities that play a role in killing the pathogen and repairing damaged tissue" (Kemeny, 2007, p. 94). These crucial proteins may also trigger fever, reduced appetite, and decreased activity, which can conserve energy and promote recovery (Marshall, 2007). But exposure to long-term stress can sometimes foster persistent overproduction of proinflammatory cytokines, which can promote chronic inflammation (Robles, Glaser, & Kiecolt-Glaser, 2005). Scientists have only begun to fully appreciate the potential ramifications of this chronic inflammation in recent years. As we noted earlier, inflammation has recently been recognized as a major factor in the development of heart disease. But that's not all. Research has also demonstrated that chronic inflammation contributes to a diverse array of diseases, including arthritis, osteoporosis, respiratory diseases, diabetes, Alzheimer's disease, and some types of cancer (Feuerstein et al., 2007). Thus, chronic inflammation resulting from immune system dysregulation may be another key mechanism underlying the association between stress and wide variety of diseases.

Sizing Up the Link Between Stress and Illness

A wealth of evidence shows that stress is related to physical health, and converging lines of evidence suggest that stress contributes to the *causation* of illness (Cohen, Janicki-Deverts, & Miller, 2007). But we have to put this intriguing finding in perspective. The vast majority of the relevant research is correlational, so it can't demonstrate *conclusively* that stress causes illness (Smith & Gallo, 2001). Subjects' elevated levels of stress and illness could both be due to a third variable, perhaps some aspect of personality (see **Figure 13.12** on the next page). For instance, some evidence suggests that neuroticism may make people overly prone to interpret events as stressful and overly prone to interpret unpleasant sensations as symptoms of illness, thus inflating the correlation between stress and illness (Turner & Wheaton, 1995).

The stress-illness correlation. One or more aspects of personality, physiology, or memory could play the role of a postulated third variable in the relationship between high stress and high incidence of illness. For example, neuroticism may lead some subjects to view more events as stressful and to remember more illness, thus inflating the apparent correlation between stress and illness.

to infectious agents and environmental toxins, nutrition, exercise, alcohol and drug use, smoking, use of medical care, and cooperation with medical advice. Furthermore, some people handle stress better than others, which is the matter we turn to next.

REVIEW of Key Points

13.11 The Type A personality has been implicated as a contributing cause of coronary heart disease, but the evidence has been equivocal. Recent research suggests that hostility may be the most toxic element of the Type A syndrome.

13.12 Transient, stress-induced emotional reactions can elicit cardiac symptoms. Although depression can be a result of heart disease, research also suggests that depression can increase one's risk for cardiovascular disease. Our Featured Study found that depression was a predictor of increased cardiac mortality.

13.13 Stress appears to play a role in a host of diseases, perhaps because it can temporarily suppress the effectiveness of the immune system. Exposure to long-term stress can also promote chronic inflammation. Although there's little doubt that stress can contribute to the development of physical illness, the link between stress and illness is modest. Stress is only one factor in a complex network of biopsychosocial variables that shape health.

In spite of methodological problems favoring inflated correlations, the research in this area consistently indicates that the *strength* of the relationship between stress and health is *modest.* The correlations typically fall in the .20s and .30s (Cohen, Kessler, & Gordon, 1995). Clearly, stress is not an irresistible force that produces inevitable effects on health. Actually, this fact should come as no surprise, as stress is but one factor operating in a complex network of biopsychosocial determinants of health. Other key factors include one's genetic endowment, exposure

Factors Moderating the Impact of Stress

Key Learning Goals

13.14 Understand how social support moderates the impact of stress.

13.15 Identify two personality factors related to stress resistance and health.

Some people seem to be able to withstand the ravages of stress better than others (Holohan & Moos, 1994). Why? Because a number of *moderator variables* can lessen the impact of stress on physical and mental health. We'll look at three key moderator variables—social support, optimism, and conscientiousness—to shed light on individual differences in how well people tolerate stress.

Social Support

Friends may be good for your health! This startling conclusion emerges from studies on social support as a moderator of stress. *Social support* refers to various types of aid and emotional sustenance provided by members of one's social networks. Many studies have found positive correlations between high social support and greater immune functioning (Uchino, Uno, & Holt-Lunstad, 1999). In contrast, the opposite of social support—loneliness and social isolation—was found to predict reduced immune responding in a recent study of college students (Pressman et al., 2005). In recent decades, a vast number of studies have found evidence that social support is favorably related to physical health (Taylor, 2007; Uchino, 2004), including all-important

coronary health (Rutledge et al., 2004). The favorable effects of social support are strong enough to have an impact on participants' mortality! For example, one study followed patients for a mean period of 4.5 years following a nonfatal heart attack and found that higher levels of perceived social support were associated with reduced mortality among patients who did not manifest depression (Lett et al., 2007). Similarly, an Australian study that tracked 1477 participants aged 70 and over for ten years found that people with richer friendship networks lived longer (Giles et al., 2005).

Social support seems to be good medicine for the mind as well as the body, as most studies also find an association between social support and mental health (Davis, Morris, & Kraus, 1998). It appears that social support serves as a protective buffer during times of high stress, reducing the negative impact of stressful events, and that social support has its own positive effects on health, which may be apparent even when people aren't under great stress (Wills & Fegan, 2001).

Of course, social *bonds* are not equivalent to social *support.* Indeed, some people in one's social circles may be a source of more *stress* than *support* (Vinokur & van Ryn, 1993). Friends and family can be argumentative, put one under pressure, make one feel

guilty, break promises, and so forth. Research suggests that social conflicts can increase susceptibility to illness (Cohen, 2004). For example, a recent study of older adults assessed the degree to which the participants had stable, consistent negative exchanges with people in their social networks (Newsom, et al., 2008). The study found that higher levels of negative interactions were predictive of lower self-rated health and of having a higher number of troublesome health conditions.

Optimism and Conscientiousness

Defining *optimism* **as a general tendency to expect good outcomes,** Michael Scheier and Charles Carver (1985) found a correlation between optimism and relatively good physical health in a sample of college students. Another study found optimism to be associated with more effective immune functioning (Segerstrom et al., 1998). Other studies have found that optimism helps people deal more effectively with a diagnosis of breast cancer (Carver et al., 2005) and with a death or onset of illness in one's immediate family (Kivimaki et al. 2005). Why is optimism beneficial to health? Research suggests that optimists cope with stress in more adaptive ways than pessimists (Aspinwall, Richter, & Hoffman, 2001; Nes & Segerstrom, 2006). Optimists are more likely to engage in action-oriented, problem-focused coping. They are more willing than pessimists to seek social support, and they are more likely to emphasize the positive in their appraisals of stressful events. In comparison, pessimists are more likely to deal with stress by giving up or engaging in denial or wishful thinking.

In a related line of research, Christopher Peterson and Martin Seligman have studied how people explain bad events (personal setbacks, mishaps, disappointments, and such). They have identified a *pessimistic explanatory style,* in which people tend to blame setbacks on their own personal shortcomings, versus an *optimistic explanatory style,* which leads people to attribute setbacks to temporary situational factors. In two retrospective studies of people born many decades ago, they found an association between an optimistic explanatory style and relatively good health (Peterson, Seligman, & Vaillant, 1988) and increased longevity (Peterson et al., 1998). Many other studies have linked this optimistic explanatory style to superior physical health (Peterson & Bossio, 2001), as well as higher academic achievement, increased job productivity, enhanced athletic performance, and higher marital satisfaction (Gillham et al., 2001).

Optimism versus pessimism is not the only dimension of personality that has been examined as a possible moderator of physical health. Howard

In times of stress, seeking support from one's friends is a very sensible and helpful coping strategy.

Friedman and his colleagues have found evidence that *conscientiousness,* one of the Big Five personality traits discussed in Chapter 12, may have an impact on physical health (Friedman et al., 1993; Martin, Friedman, & Schwartz, 2007). They have related personality measures to longevity in the gifted individuals first studied by Lewis Terman (see Chapter 9), who have been followed closely by researchers since 1921. Data were available on six personality traits, which were measured when the subjects were children. The one trait that predicted greater longevity was conscientiousness. Why does conscientiousness promote longevity? According to Friedman (2007), several considerations may contribute. For example, conscientious people may tend to gravitate to healthy environments, and they may show less reactivity to stress. But the key consideration appears to be that conscientiousness fosters better health habits. People who are high in conscientiousness are less likely than others to exhibit unhealthy habits, such as excessive drinking, drug abuse, dangerous driving, smoking, overeating, and risky sexual practices (Bogg & Roberts, 2004; Roberts, Walton, & Bogg, 2005).

Individual differences among people in social support, optimism, and conscientiousness explain why stress doesn't have the same impact on everyone. Differences in lifestyle may play an even larger role in determining health. We'll examine some critical aspects of lifestyle in the next section.

Martin Seligman

"The concept of explanatory style brings hope into the laboratory, where scientists can dissect it in order to understand how it works."

REVIEW of Key Points

13.14 There are individual differences in how much stress people can tolerate without experiencing ill effects. Social support is a key moderator of the relationship between stress and both physical and mental health. Studies have even found that social support is related to mortality. Social support buffers the effects of stress and has its own positive effects on health.

13.15 Optimism is associated with relatively good physical health. Optimism may lead to more effective coping with stress, whereas pessimism has been related to passive coping and poor health practices. A study of Terman's sample of gifted children suggests that conscientiousness is associated with greater longevity. Conscientiousness appears to be related to better health habits.

Key Learning Goals

13.16 Explain the negative impact of smoking on health.

13.17 Discuss how poor nutrition and lack of exercise are related to physical health.

13.18 Clarify the relationship between behavioral factors and AIDS.

13.19 Understand how health-impairing lifestyles develop.

Health-Impairing Behavior

Some people seem determined to dig an early grave for themselves. They do precisely those things that are bad for their health. For example, some people drink heavily even though they know that they're damaging their liver. Others eat all the wrong foods even though they know that they're increasing their risk of a second heart attack. Behavior that's downright *self-destructive* is surprisingly common. In this section we'll discuss how health is affected by smoking, nutrition, exercise, and drug use, and we'll look at behavioral factors in AIDS. We'll also discuss *why* people develop health-impairing lifestyles.

Smoking

The percentage of people who smoke has declined noticeably since the mid-1960s (see **Figure 13.13**). Nonetheless, about 24% of adult men and 18% of adult women in the United States continue to smoke regularly. Unfortunately, these figures are slightly higher (28% for both sexes) among college students (Rigotti, Lee, & Wechsler, 2000). Moreover, smoking is even more common in many other societies.

The evidence clearly shows that smokers face a much greater risk of premature death than nonsmokers. For example, the average smoker has an estimated life expectancy *13–14 years shorter* than that of a similar nonsmoker (Schmitz & Delaune, 2005). The overall risk is positively correlated with the number of cigarettes smoked and their tar and nicotine content. Cigar smoking, which has increased dramatically in recent years, elevates health risks almost as much as cigarette smoking (Baker et al., 2000).

Why are mortality rates higher for smokers? Smoking increases the likelihood of developing a surprisingly large range of diseases (Schmitz & Delaune, 2005; Woloshin, Schwartz, & Welch, 2002). Lung cancer and heart disease kill the largest number of smokers. However, smokers also have an elevated risk for oral, bladder, and kidney cancer, as well as cancers of the larynx, esophagus, and pancreas; for arteriosclerosis, hypertension, stroke, and other cardiovascular diseases; and for bronchitis, emphysema, and other pulmonary diseases. Most smokers know about the risks associated with tobacco use, but they tend to underestimate the actual risks as applied to themselves (Ayanian & Cleary, 1999). They also tend to overestimate the likelihood that they can quit smoking when they decide to (Weinstein, Slovic, & Gibson, 2004).

Studies show that if people can give up smoking, their health risks decline reasonably quickly (Kenfield et al., 2008; Williams et al., 2002; see **Figure 13.14**). Evidence suggests that most smokers would like to quit but are reluctant to give up a major source of pleasure, and they worry about craving cigarettes, gaining weight, becoming anxious and irritable, and feeling less able to cope with stress (Grunberg, Faraday, & Rahman, 2001).

Unfortunately, it's difficult to give up cigarettes. People who enroll in formal smoking cessation programs are only slightly more successful than people who try to quit on their own (Swan, Hudmon, Khroyan, 2003). Long-term success rates are in the vicinity of only 25%, and some studies report even lower figures. For example, in one study of self-quitters, after six months only 3% had maintained complete abstinence from smoking (Hughes et al., 1992). Nonetheless, the fact that there are nearly 40 million ex-smokers in the United States indicates that it is possible to quit smoking successfully. Interestingly, many people fail several or more times before they eventually succeed. Evidence suggests that the readiness to give up smoking builds gradually as people cycle through periods of abstinence and relapse (Prochaska, 1994; Prochaska et al., 2004).

Poor Nutritional Habits

Evidence is accumulating that patterns of nutrition influence susceptibility to a variety of diseases and health problems. For example, in a study of over 42,000 women, investigators found an association

Figure 13.13

The prevalence of smoking in the United States. This graph shows how the percentage of U.S. adults who smoke has declined steadily since the mid-1960s. Although considerable progress has been made, smoking still accounts for a huge number of premature deaths each year. (Based on data from the Centers for Disease Control and Prevention)

between a measure of overall diet quality and mortality. Women who reported poorer quality diets had elevated mortality rates (Kant et al., 2000). What are the specific links between diet and health? In addition to the problems associated with obesity, which we discussed in Chapter 10, other possible connections between eating patterns and health include the following:

1. Heavy consumption of foods that elevate serum cholesterol level (eggs, cheeses, butter, shellfish, sausage, and the like) appears to increase the risk of cardiovascular disease (Stamler et al., 2000; see **Figure 13.15**). Eating habits are only one of several factors that influence serum cholesterol level, but they do make an important contribution.

2. Vulnerability to cardiovascular diseases may also be influenced by other dietary factors. For example, low-fiber diets may increase the likelihood of coronary disease (Timm & Slavin, 2008), and high intake of red and processed meats, sweets, potatoes, and refined grains is associated with increased cardiovascular risk (Hu & Willett, 2002). Recent research indicates that the omega 3 fatty acids found in fish and fish oils offer some protection against coronary disease (Din, Newby, & Flapan, 2004) and are also associated with reduced risk for arthritis, autoimmune diseases, and some types of cancer (Umhau & Dauphinais, 2007).

3. High salt intake is a contributing factor in the development of high blood pressure, referred to medically as hypertension (Havas, Dickinson, & Wilson, 2007). Many people only worry about the salt that they add at the table, but in the typical American diet that accounts for only 6% of salt intake (77% comes from processed and restaurant foods).

4. High caffeine consumption may elevate one's risk for hypertension (James, 2004) and for coronary disease (Happonen, Voutilainen, & Salonen, 2004), although the negative effects of caffeine appear relatively modest.

5. High-fat diets have been implicated as possible contributors to cardiovascular disease (Melanson, 2007) and to some forms of cancer, especially prostate cancer (Rose, 1997), colon and rectal cancer (Shike, 1999), and breast cancer (Wynder et al., 1997). Some studies also suggest that high-fiber diets may reduce one's risk for breast cancer, colon cancer, and diabetes (Timm & Slavin, 2008).

Of course, nutritional habits interact with other factors—genetics, exercise, environment, and so on—to determine whether one develops a particular disease. Nonetheless, the examples just described indicate that eating habits can influence one's physical health.
Figure 13.14
Quitting smoking and health risk. Research suggests that various types of health risks associated with smoking decline gradually after people give up tobacco. The data shown here, from the 1990 U.S. Surgeon General's report on smoking, illustrate the overall effects on mortality rates. (Based on data from U.S. Department of Health and Human Services, 1990)

Lack of Exercise

Considerable evidence links lack of exercise to poor health. Research indicates that regular exercise is associated with increased longevity. For example, a recent study of over 15,000 men found that those who were high in fitness had a 70% reduction in mortality compared to those who were low in fitness (Kokkinos et al., 2008). Exercise provides similar benefits for women (Mora et al., 2007). Why would exercise help people live longer? For one thing, an appropriate exercise program can enhance cardiovascular fitness and thereby reduce susceptibility to deadly cardiovascular problems (Zoeller, 2007). Second, exercise may indirectly reduce one's risk for a variety of obesity-related health problems, such as diabetes and respiratory difficulties (Corsica & Perri, 2003). Third, recent studies suggest that exercise can help
Figure 13.15
The link between cholesterol and coronary risk. In a review of several major studies, Stamler et al. (2000) summarize crucial evidence on the association between cholesterol levels and the prevalence of cardiovascular disease. This graph is based on a sample of over 11,000 men who were ages 18 to 39 at the beginning of the study (1967–1973) when their serum cholesterol level was measured. The data shown here depict participants' relative risk for coronary heart disease during the ensuing 25 years, as a function of their initial cholesterol level.

diminish chronic inflammation, which is thought to contribute to quite a variety of diseases (Flynn, McFarlin, & Markofski, 2007). Fourth, exercise can serve as a buffer that reduces the potentially damaging physical effects of stress (Plante, Caputo, & Chizmar, 2000). This buffering effect may occur because people high in fitness show less physiological reactivity to stress than those who are less fit (Forcier et al., 2006). If these payoffs weren't enough to get people hustling to the gym, recent studies have turned up a new, unexpected benefit of exercise—it can facilitate the generation of new brain cells (Cotman, Berchtold, & Christie, 2007; Pereira et al., 2007). As noted earlier in the chapter (see p. 544), *neurogenesis* appears to be an important process that can be suppressed by stress. The finding that this neurodevelopmental process can be promoted by simple exercise may turn out to have profound implications.

Alcohol and Drug Use

Recreational drug use is another common health-impairing habit. The risks associated with the use of various drugs were discussed in detail in Chapter 5. Unlike smoking, poor eating habits, and inactivity, drugs can kill directly and immediately when they are taken in an overdose or when they impair the user enough to cause an accident. In the long run, various recreational drugs may also elevate one's risk for infectious diseases; respiratory, pulmonary, and cardiovascular diseases; liver disease; gastrointestinal problems; cancer; neurological disorders; and pregnancy complications (see Chapter 5). Ironically, the greatest physical damage in the population as a whole is caused by alcohol, the one recreational drug that's legal.

Behavior and AIDS

Some of the most problematic links between behavior and health may be those related to AIDS. AIDS stands for *acquired immune deficiency syndrome, a disorder in which the immune system is gradually weakened and eventually disabled by the human immunodeficiency virus (HIV).* Being infected with the HIV virus is *not* equivalent to having AIDS, which is the final stage of the HIV infection process, typically manifested years after the original infection (Carey & Vanable, 2003). With the onset of AIDS, one is left virtually defenseless against a variety of opportunistic infectious agents. AIDS inflicts its harm indirectly by opening the door to other diseases. The symptoms of AIDS vary widely,

depending on the specific constellation of diseases that one develops (Cunningham & Selwyn, 2005). Unfortunately, the worldwide prevalence of this deadly disease continues to increase at an alarming rate, especially in certain regions of Africa (UNAIDS, 2006).

Prior to 1996–1997, the average length of survival for people after the onset of the AIDS syndrome was about 18 to 24 months. Encouraging advances in the treatment of AIDS with drug regimens referred to as *highly active antiretroviral therapy (HAART)* hold out promise for *substantially* longer survival (Anthony & Bell, 2008; Hammer et al., 2006). But these drugs have been rushed into service, and their long-term efficacy is yet to be determined. Medical experts are concerned that the general public has gotten the impression that these treatments have transformed AIDS from a fatal disease to a manageable one, which may be a premature conclusion. HIV strains are evolving, and many have developed resistance to the currently available antiretroviral drugs. Moreover, some patients do not respond well to the new drugs, and many patients who are responsive have difficulty sticking to drug regimens that often have adverse side effects (Beusterien et al., 2008; Hammer et al., 2006).

Transmission

The HIV virus is transmitted through person-to-person contact involving the exchange of bodily fluids, primarily semen and blood. The two principal modes of transmission in the United States have been sexual contact and the sharing of needles by intravenous (IV) drug users. In the United States, sexual transmission has occurred primarily among gay and bisexual men, but heterosexual transmission has increased in recent years (Centers for Disease Control, 2006). In the world as a whole, infection through heterosexual relations has been much more common from the beginning. In heterosexual relations, male-to-female transmission is estimated to be about eight times more likely than female-to-male transmission (Ickovics, Thayaparan, & Ethier, 2001). The HIV virus can be found in the tears and saliva of infected individuals, but the concentrations are low, and there is no evidence that the infection can be spread through casual contact. Even most forms of noncasual contact, including kissing, hugging, and sharing food with infected individuals, appear safe.

Misconceptions

Misconceptions about AIDS are widespread. Ironically, the people who hold these misconceptions fall

into two polarized camps. On the one hand, a great many people have unrealistic fears that AIDS can be readily transmitted through casual contact with infected individuals. These people worry unnecessarily about contracting AIDS from a handshake, a sneeze, or an eating utensil, and they tend to be paranoid about interacting with homosexuals, thus fueling discrimination against gays.

On the other hand, many young heterosexuals who are sexually active with a variety of partners foolishly downplay their risk for HIV, naively assuming that they are safe as long as they avoid IV drug use and sexual relations with gay or bisexual men. They greatly underestimate the probability that their sexual partners previously may have used IV drugs or had unprotected sex with an infected individual. Also, because AIDS is usually accompanied by discernible symptoms, many young people believe that prospective sexual partners who carry the HIV virus will exhibit telltale signs of illness, but that is generally not the case. In reality, many HIV carriers do not know themselves that they are HIV-positive. In a recent study that screened over 5000 men for HIV, 77% of those who tested HIV-positive were previously unaware of their infection (MacKellar et al., 2005). In sum, many myths about AIDS persist, in spite of extensive efforts to educate the public about this complex and controversial disease. **Figure 13.16** contains a short quiz to test your knowledge of the facts about AIDS.

Prevention

The behavioral changes that minimize the risk of developing AIDS are fairly straightforward, although making the changes is often much easier said than done. In all groups, the more sexual partners a person has, the higher the risk that one will be exposed to the HIV virus. Thus, people can reduce their risk by having sexual contacts with fewer partners and by using condoms to control the exchange of semen. It is also important to curtail certain sexual practices (in particular, anal sex) that increase the probability of semen/blood mixing. The 1980s and early 1990s saw considerable progress toward wider use of safe sex practices, but new cohorts of young people appear to be much less concerned about the risk of HIV infection than the generation that witnessed the original emergence of AIDS (Jaffe, Valdiserri, & De Cock, 2007). In particular, experts are concerned that recent advances in treatment may lead to more casual attitudes about risky sexual practices, a development that would not bode well for public health efforts to slow the spread of AIDS (Kalichman et al., 2007; van Kesteren, Hospers, & Kok, 2007).

AIDS Risk Knowledge Test

Answer the following "true" or "false."

T F   **1.** The AIDS virus cannot be spread through kissing.
T F   **2.** A person can get the AIDS virus by sharing kitchens and bathrooms with someone who has AIDS.
T F   **3.** Men can give the AIDS virus to women.
T F   **4.** The AIDS virus attacks the body's ability to fight off diseases.
T F   **5.** You can get the AIDS virus by someone sneezing, like a cold or the flu.
T F   **6.** You can get AIDS by touching a person with AIDS.
T F   **7.** Women can give the AIDS virus to men.
T F   **8.** A person who got the AIDS virus from shooting up drugs cannot give the virus to someone by having sex.
T F   **9.** A pregnant woman can give the AIDS virus to her unborn baby.
T F **10.** Most types of birth control also protect against getting the AIDS virus.
T F **11.** Condoms make intercourse completely safe.
T F **12.** Oral sex is safe if partners "do not swallow."
T F **13.** A person must have many different sexual partners to be at risk for AIDS.
T F **14.** It is more important to take precautions against AIDS in large cities than in small cities.
T F **15.** A positive result on the AIDS virus antibody test often occurs for people who do not even have the virus.
T F **16.** Only receptive (passive) anal intercourse transmits the AIDS virus.
T F **17.** Donating blood carries no AIDS risk for the donor.
T F **18.** Most people who have the AIDS virus look quite ill.

How Does Health-Impairing Behavior Develop?

It may seem puzzling that people behave in self-destructive ways. How does this happen? Several factors are involved. First, many health-impairing habits creep up on people slowly. For instance, drug use may grow imperceptibly over years, or exercise habits may decline ever so gradually. Second, many health-impairing habits involve activities that are quite pleasant at the time. Actions such as eating favorite foods, smoking cigarettes, or getting "high" are potent reinforcing events. Third, the risks associated with most health-impairing habits are chronic diseases such as cancer that usually lie 10, 20, or 30 years down the road. It's relatively easy to ignore risks that lie in the distant future.

Finally, people have a curious tendency to underestimate the risks that accompany their own health-impairing behaviors while viewing the risks associated with others' self-destructive behaviors much more accurately (Weinstein, 2003; Weinstein & Klein, 1996). Many people are well aware of the dangers associated with certain habits, but when it's time to apply this information to themselves, they often discount it. They figure, for instance, that smoking will lead to cancer or a heart attack in *someone else.*

So far, we've seen that physical health may be affected by stress and by aspects of lifestyle. Next, we'll look at the importance of how people react to physical symptoms, health problems, and health care efforts.

Reactions to Illness

Key Learning Goals

13.20 Discuss individual differences in the willingness to seek medical treatment.

13.21 Describe some barriers to effective patient-provider communication and ways to overcome these problems.

13.22 Review the extent to which people tend to adhere to medical advice.

Some people respond to physical symptoms and illnesses by ignoring warning signs of developing diseases, while others engage in active coping efforts to conquer their diseases. Let's examine the decision to seek medical treatment, communication with health providers, and compliance with medical advice.

Deciding to Seek Treatment

Have you ever experienced nausea, diarrhea, stiffness, headaches, cramps, chest pains, or sinus problems? Of course you have; we all experience some of these problems periodically. However, whether someone views these sensations as *symptoms* is a matter of individual interpretation. When two persons experience the same unpleasant sensations, one may shrug them off as a nuisance while the other may rush to a physician (Martin & Leventhal, 2004). Studies suggest that people who are relatively high in anxiety and neuroticism tend to report more symptoms of illness than others do (Petrie & Pennebaker, 2004). Those who are extremely attentive to bodily sensations and health concerns also report more symptoms than the average person (Barsky, 1988).

Variations in the perceived seriousness and disruptiveness of symptoms help explain the differences among people in their readiness to seek medical treatment (Cameron, Leventhal, & Leventhal, 1993). The biggest problem in regard to treatment seeking is the tendency of many people to delay the pursuit of needed professional consultation. Delays can be critical, because early diagnosis and quick intervention may facilitate more effective treatment of many health problems (Petrie & Pennebaker, 2004). Unfortunately, procrastination is the norm even when people are faced with a medical emergency, such as a heart attack (Martin & Leventhal, 2004). Why do people dawdle in the midst of a crisis?

Robin DiMatteo (1991), a leading expert on patient behavior, mentions a number of reasons, noting that people delay because they often (a) misinterpret and downplay the significance of their symptoms, (b) fret about looking silly if the problem turns out to be nothing, (c) worry about "bothering" their physician, (d) are reluctant to disrupt their plans (to go out to dinner, see a movie, and so forth), and (e) waste time on trivial matters (such as taking a shower, gathering personal items, or packing clothes) before going to a hospital emergency room.

Communicating with Health Providers

A large portion of medical patients leave their doctors' offices not understanding what they have been told and what they are supposed to do (Johnson & Carlson, 2004). This situation is unfortunate, because good communication is a crucial requirement for sound medical decisions, informed choices about treatment, and appropriate follow-through by patients (Buckman, 2002; Gambone, Reiter, & DiMatteo, 1994).

There are many barriers to effective provider-patient communication (DiMatteo, 1997; Marteau & Weinman, 2004). Economic realities dictate that medical visits are generally quite brief, allowing little time for discussion. Many providers use too much medical jargon and overestimate their patients' understanding of technical terms. Patients who are upset and worried about their illness may simply forget to report some symptoms or to ask questions they meant to ask. Other patients are evasive about their real concerns because they fear a serious diagnosis. Many patients are reluctant to challenge doctors' authority and are too passive in their interactions with providers.

Communication between health care providers and patients tends to be far from optimal, for a variety of reasons.

What can you do to improve your communication with health care providers? The key is to not be a passive consumer of medical services (Ferguson, 1993; Kane, 1991). Arrive at a medical visit on time, with your questions and concerns prepared in advance. Try to be accurate and candid in replying to your doctor's questions. If you don't understand something the doctor says, don't be embarrassed about asking for clarification. If you have doubts about the suitability or feasibility of your doctor's recommendations, don't be afraid to voice them.

Adhering to Medical Advice

Many patients fail to adhere to the instructions they receive from physicians and other health care professionals. The evidence suggests that noncompliance with medical advice may occur 30% of the time when short-term treatments are prescribed for acute conditions and 50% of the time when long-term treatments are needed for chronic illness (Johnson & Carlson, 2004). Nonadherence takes many forms. Patients may fail to begin a treatment regimen, stop the regimen early, reduce or increase the levels of treatment that were prescribed, or be inconsistent and unreliable in following treatment procedures (Dunbar-Jacob & Schlenk, 2001). Nonadherence is a major problem in our medical care system that has been linked to increased sickness, treatment failures,

and higher mortality (Christensen & Johnson, 2002; DiMatteo et al., 2002). Moreover, nonadherence wastes expensive medical visits and medications and increases hospital admissions, leading to enormous economic costs. DiMatteo (2004b) speculates that in the United States alone, nonadherence may be a $300 billion a year drain on the health care system.

Concern about nonadherence does not mean that patients should passively accept all professional advice from medical personnel. However, when patients have doubts about a prescribed treatment, they should speak up and ask questions. Passive resistance can backfire. For instance, if a physician sees no improvement in a patient who falsely insists that he has been taking his medicine, the physician may abandon an accurate diagnosis in favor of an inaccurate one. The inaccurate diagnosis could then lead to inappropriate treatments that might be harmful to the patient.

Why don't people comply with the advice that they've sought out from highly regarded health care professionals? Physicians tend to attribute noncompliance to patients' personal characteristics, but research indicates that personality traits and demographic factors are surprisingly unrelated to adherence rates (DiMatteo, 2004b; Marteau & Weinman, 2004). One factor that *is* related to adherence is patients' *social support.* Adherence is improved when patients have family members, friends, or co-workers who remind them and help them to comply with treatment requirements (DiMatteo, 2004a). Several

Robin DiMatteo

"A person will not carry out a health behavior if significant barriers stand in the way, or if the steps interfere with favorite or necessary activities."

other considerations can adversely influence the likelihood of adherence (Dunbar-Jacob & Schlenk, 2001; Johnson & Carlson, 2004):

1. *Frequently, noncompliance is a result of the patient's failure to understand the instructions as given.* Highly trained professionals often forget that what seems obvious and simple to them may be obscure and complicated to many of their patients.

2. *Another key factor is how aversive or difficult the instructions are.* If the prescribed regimen is unpleasant, compliance will tend to decrease. And the more that following instructions interferes with routine behavior, the less probable it is that the patient will cooperate successfully.

3. *If a patient has a negative attitude toward a physician, the probability of noncompliance will increase.*

When patients are unhappy with their interactions with the doctor, they're more likely to ignore the medical advice provided.

In response to the noncompliance problem, researchers have investigated many methods of increasing patients' adherence to medical advice. Interventions have included simplifying instructions, providing more rationale for instructions, reducing the complexity of treatment regimens, helping patients with emotional distress that undermines adherence, and training patients in the use of behavior modification strategies. All of these interventions can improve adherence, although their effects tend to be modest (Christensen & Johnson, 2002; Roter et al., 1998).

REVIEW of Key Points

13.20 People high in anxiety or neuroticism report more symptoms of illness than others. The biggest problem in regard to treatment seeking is the tendency of many people to delay the pursuit of needed treatment.

13.21 There are many barriers to effective communication between patients and health care providers, such as brief visits, overdependence on medical jargon, and patients' evasiveness

and forgetfulness. The key for patients in improving communication is to not be a passive consumer of medical services.

13.22 Noncompliance with medical advice is a major problem, which may occur 30% of the time in the context of short-term treatments and 50% of the time in long-term treatments. The likelihood of nonadherence is greater when instructions are difficult to understand, when recommendations are difficult to follow, and when patients are unhappy with their doctor.

Reflecting on the Chapter's Themes

Key Learning Goals

13.23 Identify the two unifying themes highlighted in this chapter.

Multifactorial Causation

Subjectivity of Experience

Which of our themes were prominent in this chapter? As you probably noticed, our discussion of stress and health illustrated multifactorial causation and the subjectivity of experience. As we noted in Chapter 1, people tend to think simplistically, in terms of single causes. In recent years, the highly publicized research linking stress to health has led many people to point automatically to stress as an explanation for illness. In reality, stress has only a modest impact on physical health. Stress can increase the risk for illness, but health is governed by a dense network of factors. Important factors include inherited vulnerabilities, physiological reactivity, exposure to infectious agents, health-impairing habits, reactions to symptoms, treatment-seeking behavior, compliance with medical advice, personality, and social support. In other words, stress is but one actor on a crowded stage. This should be apparent in **Figure 13.17**, which shows the multitude of biopsychosocial factors that jointly influence physical health. It illustrates multifactorial causation in all its complexity.

The subjectivity of experience was demonstrated by the frequently repeated point that stress lies in the eye of the beholder. The same job promotion may be stressful for one person and invigorating for another. One person's pressure is another's challenge. When it comes to stress, objective reality is not nearly as important as subjective perceptions. More than anything else, the impact of stressful events seems to depend on how people view them. The critical importance of individual stress appraisals will continue to be apparent in the Personal Application on coping and stress management. Many stress management strategies depend on altering one's appraisals of events.

REVIEW of Key Points

13.23 Two of our integrative themes were prominent in this chapter. First, we saw that behavior and health are influenced by multiple causes. Second, we saw that experience is highly subjective, as stress lies in the eye of the beholder.
Figure 13.17

Biopsychosocial factors in health. Physical health can be influenced by a remarkably diverse set of variables, including biological, psychological, and social factors. The host of factors that affect health provide an excellent example of multifactorial causation.

Improving Coping and Stress Management

Answer the following "true" or "false."

____ **1** The key to managing stress is to avoid or circumvent it.

____ **2** It's best to suppress emotional reactions to stress.

____ **3** Laughing at one's problems is immature.

Courses and books on stress management have multiplied at a furious pace in the last couple of decades. They summarize experts' advice on how to cope with stress more effectively. How do these experts feel about the three statements above? As you'll see in this Application, most would agree that all three are false.

The key to managing stress does *not* lie in avoiding it. Stress is an inevitable element in the fabric of modern life. As Hans Selye (1973) noted, "Contrary to public opinion, we must not—and indeed can't—avoid stress" (p. 693). Thus, most stress management programs encourage people

to confront stress rather than sidestep it. Doing so requires training people to engage in action-oriented, rational, reality-based *constructive coping.* Fortunately, research suggests that stress management training can be beneficial in reducing the potential negative effects of stress (Evers et al., 2006; Storch et al., 2007).

As we noted earlier, some coping tactics are more healthful than others. In this Application, we'll examine a variety of constructive coping tactics, beginning with Albert Ellis's ideas about changing one's appraisals of stressful events.

Reappraisal: Ellis's Rational Thinking

Albert Ellis is a prominent theorist who believes that people can short-circuit their emotional reactions to stress by altering their appraisals of stressful events. Ellis's insights about stress appraisal are the foun-

dation for a widely used system of therapy, called *rational-emotive behavior therapy* (Ellis, 1977, 1987), and several popular books on effective coping (Ellis, 1985, 1999, 2001).

Ellis maintains that *you feel the way you think*. He argues that problematic emotional reactions are caused by negative self-talk, which he calls catastrophic thinking. ***Catastrophic thinking* involves unrealistically pessimistic appraisals of stress that exaggerate the magnitude of one's problems.** According to Ellis, people unwittingly believe that stressful events cause their emotional turmoil, but he maintains that emotional reactions to personal setbacks are

Figure 13.18

Albert Ellis's A-B-C model of emotional reactions. Although most people attribute their negative emotional reactions directly to negative events that they experience, Ellis argues that events themselves do *not* cause emotional distress; rather, distress is caused by the way people *think* about negative events. According to Ellis, the key to managing stress is to change one's appraisal of stressful events.

The commonsense view

A Activating event
Stress:
Someone stands you up on a date you looked forward to.

C Consequence
Emotional turmoil:
You feel angry, anxious, agitated, dejected.

Ellis's view

A Activating event
Stress:
Someone stands you up on a date you looked forward to.

B Belief system
Irrational appraisal:
"This is terrible. I'll have a boring weekend. I'll never find anyone. I must be a worthless person."

Rational appraisal:
"This is unfortunate but I'll salvage the weekend. Someday I'll find someone who is mature and dependable."

C Consequence
Emotional turmoil:
You feel angry, anxious, agitated, dejected.

Emotional calm:
You feel annoyed and subdued but remain hopeful.

actually caused by overly negative appraisals of stressful events (see **Figure 13.18**).

Ellis theorizes that unrealistic appraisals of stress are derived from irrational assumptions that people hold. He maintains that if you scrutinize your catastrophic thinking, you'll find that your reasoning is based on a logically indefensible premise, such as "I must have approval from everyone" or "I must perform well in all endeavors." These faulty assumptions, which people often hold unconsciously, generate catastrophic thinking and emotional turmoil. How can you reduce your unrealistic appraisals of stress? Ellis asserts that you must learn (1) how to detect catastrophic thinking and (2) how to dispute the irrational assumptions that cause it.

Using Humor as a Stress Reducer

A number of years ago, the Chicago area experienced its worst flooding in about a cen-

tury. Thousands of people saw their homes wrecked when two rivers spilled over their banks. As the waters receded, the flood victims returning to their homes were subjected to the inevitable TV interviews. A remarkable number of victims, surrounded by the ruins of their homes, *joked* about their misfortune. When the going gets tough, it may pay to laugh about it. In a study of cop-

ing styles, McCrae (1984) found that 40% of his subjects used humor to deal with stress.

Empirical evidence showing that humor moderates the impact of stress has been accumulating over the last 25 years (Abel, 1998; Lefcourt, 2001). How does humor help to reduce the effects of stress and promote wellness? Several explanations have been proposed (see **Figure 13.19**). One possibility

People often turn to humor to help themselves cope during difficult times, as this photo taken in the aftermath of Hurricane Katrina illustrates. Research suggests that humor can help to reduce the negative impact of stressful events.

© Radhika Chalasani/Getty Images

Possible explanations for the link between humor and wellness. Research suggests that a good sense of humor buffers the effects of stress and promotes wellness. Four hypothesized explanations for the link between humor and wellness are outlined in the middle column of this diagram. As you can see, humor may have a variety of beneficial effects.

is that humor affects appraisals of stressful events (Abel, 2002). Jokes can help people to put a less threatening spin on their trials and tribulations. Another possibility is that humor increases the experience of positive emotions (Martin, 2002), which can help people bounce back from stressful events (Tugade & Fredrickson, 2004). Another hypothesis is that a good sense of humor facilitates rewarding social interactions, which promote social support, which is known to buffer the effects of stress (Martin, 2002). Finally, Lefcourt and colleagues (1995) argue that high-humor people may benefit from not taking themselves as seriously as low-humor people do. As they put it, "If persons do not regard themselves too seriously and do not have an inflated sense of self-importance, then defeats, embarrassments, and even tragedies should have less pervasive emotional consequences for them" (p. 375).

Releasing Pent-Up Emotions and Forgiving Others

As we discussed in the main body of the chapter, stress often leads to emotional arousal. When this happens, there's merit in the commonsense notion that you should try to release the emotions welling up inside. Why? Because the physiological arousal that accompanies emotions can become problematic. For example, research suggests that people who inhibit the expression of anger and other emotions are somewhat more likely than other people to have elevated blood pressure (Jorgensen et al., 1996). Moreover, research suggests that efforts to actively suppress emotions result in increased stress and autonomic arousal (Butler et al., 2003; Gross, 2001) and, ultimately, the experience of more negative emotions and fewer positive emotions (John & Gross, 2007).

Although there's no guarantee of it, you can sometimes reduce your physiological arousal by *expressing* your emotions. Evidence is accumulating that writing or talking about life's difficulties can be valuable in dealing with stress (Lyubomirsky, Sousa, & Dickerhoof, 2006; Smyth & Pennebaker, 1999). For example, in one study of college students, half the subjects were asked to write three essays about their difficulties in adjusting to college. The other half wrote three essays about superficial topics. The subjects who wrote about their personal problems enjoyed better health in the following months than the other subjects did (Pennebaker, Colder, & Sharp, 1990). Subsequent studies have replicated this finding and shown that emotional disclosure is associated with better immune functioning (Slatcher & Pennebaker, 2005; Smyth & Pennebaker, 2001). So, if you can find a good listener, you may be able to discharge problematic emotions by letting your secret fears, misgivings, and suspicions spill out in a candid conversation.

People tend to experience hostility and other negative emotions when they feel "wronged"—that is, when they believe that

In September 1994, Reg and Maggie Green were vacationing in Italy when their seven-year-old son Nicholas was shot and killed during a highway robbery. In an act of forgiveness that stunned Europe, the Greens chose to donate their son's organs, which went to seven Italians. The Greens, shown here five years after the incident, have weathered their horrific loss better than most, perhaps in part because of their willingness to forgive.

the actions of another person were harmful, immoral, or unjust. People's natural inclination in such situations is either to seek revenge or to avoid further contact with the offender (McCullough, 2001). *Forgiving* someone involves counteracting these natural tendencies and releasing the person from further liability for his or her transgression. Research suggests that forgiving is associated with better adjustment and well-being (McCullough & Witvliet, 2002; Worthington & Scherer, 2004), including enhanced mood and reduced physical symptoms (Bono, McCullough, & Root, 2008). For example, in one study of divorced or permanently separated women reported by McCullough (2001), the extent to which the women had forgiven their former husbands was positively related to several measures of well-being and inversely related to measures of anxiety and depression. Research also shows that vengefulness is correlated with more rumination and negative emotion and with lower life satisfaction (McCullough et al., 2001). Taken together, these findings suggest that it may be healthful for people to learn to forgive others more readily.

Learning to Relax

Relaxation is a valuable stress management technique that can soothe emotional turmoil and reduce problematic physiological arousal (McGuigan & Lehrer, 2007; Smith, 2007). The value of relaxation became apparent to Herbert Benson (1975; Benson & Klipper, 1988) as a result of his research on meditation. Benson, a Harvard Medical School cardiologist, believes that relaxation is the key to the beneficial effects of meditation. According to Benson, the elaborate religious rituals and beliefs associated with meditation are irrelevant to its effects. After "demystifying" meditation, Benson set out to devise a simple, nonreligious procedure that could provide similar benefits. He calls his procedure the *relaxation response*. Although there are several other worthwhile approaches to relaxation training, we'll examine Benson's procedure, as its simplicity makes it especially useful. From his study of a variety of relaxation techniques, Benson concluded that four factors promote effective relaxation:

1. *A quiet environment.* It's easiest to induce the relaxation response in a distraction-free environment. After you become experienced with the relaxation response, you may be able to practice it in a crowded subway. Initially, however, you should practice it in a quiet, calm place.

2. *A mental device.* To shift attention inward and keep it there, you need to focus your attention on a constant stimulus, such as a sound or word recited repetitively.

3. *A passive attitude.* It's important not to get upset when your attention strays to distracting thoughts. You must realize that such distractions are inevitable. Whenever your mind wanders from your attentional focus, calmly redirect attention to your mental device.

4. *A comfortable position.* Reasonable body comfort is essential to avoid a major source of potential distraction. Simply sitting up straight generally works well. Lying down is too conducive to sleep.

Benson's simple relaxation procedure is described in **Figure 13.20**. For full benefit, it should be practiced daily.

Figure 13.20

Benson's relaxation procedure. Herbert Benson's relaxation procedure is described here. According to Benson, his simple relaxation response can yield benefits similar to meditation. To experience these benefits, you should practice the procedure daily.

SOURCE: Benson, H., & Klipper, M. Z. (1975, 1988). *The relaxation response.* New York: Morrow. Copyright © 1975 by William Morrow & Co. Reprinted by permission of HarperCollins Publishers.

1 Sit quietly in a comfortable position.

2 Close your eyes.

3 Deeply relax all your muscles, beginning at your feet and progressing up to your face. Keep them relaxed.

4 Breathe through your nose. Become aware of your breathing. As you breathe out, say the word "one" silently to yourself. For example, breath in . . . out, "one"; in . . . out, "one"; and so forth. Breathe easily and naturally.

5 Continue for 10 to 20 minutes. You may open your eyes to check the time, but do not use an alarm. When you finish, sit quietly for several minutes, at first with your eyes closed and later with your eyes opened. Do not stand up for a few minutes.

6 Do not worry about whether you are successful in achieving a deep level of relaxation. Maintain a passive attitude and permit relaxation to occur at its own pace. When distracting thoughts occur, try to ignore them by not dwelling on them, and return to repeating "one." With practice, the response should come with little effort. Practice the technique once or twice daily but not within two hours after any meal, since digestive processes seem to interfere with the elicitation of the relaxation response.

Figure 13.21

Physical fitness and mortality. Blair and colleagues (1989) studied death rates among men and women who exhibited low, medium, or high fitness. As you can see, fitness was associated with lower mortality rates in both sexes.

SOURCE: Adapted from Blair, S. N., Kohl, W. H., Paffenbarger, R. S., Clark, D. G., Cooper, K. H., & Gibbons, L. W. (1989). Physical fitness and all-cause mortality. *Journal of the American Medical Association, 262,* 2395–2401. Copyright © 1989 American Medical Association. Reprinted by permission. (Photos: left, © C. H. Wooley; middle, © Paul Francis Photo; right, © Michael Newman/PhotoEdit)

Low fitness: Group 1

Medium fitness: Groups 2 and 3

High fitness: Groups 4 and 5

Participants were divided into five categories based on their fitness, ranging from least fit (group 1) to most fit (group 5).

Minimizing Physiological Vulnerability

Your body is intimately involved in your response to stress, and the wear and tear of stress can be injurious to your health. To combat this potential problem, it helps to keep your body in relatively sound shape. It's a good idea to consume a nutritionally balanced diet, get adequate sleep, and engage in at least a moderate amount of exercise. It's also a good idea to learn how to control overeating and the use of tobacco, alcohol, and other drugs. Good health habits will not make you immune to the ravages of stress. However, poor health habits generally will increase your vulnerability to stress-related diseases. We've discussed sleep patterns, drug use, and eating habits in other chapters, so the coverage here will focus exclusively on exercise.

The potential benefits of regular exercise are substantial. Fortunately, evidence indicates that you don't have to be a dedicated athlete to benefit from exercise. Even a mod-erate amount of exercise—such as taking a brisk, half-hour walk each day—can reduce your risk of disease (Richardson et al., 2004; see **Figure 13.21**). Successful participation in an exercise program can also lead to improvements in your mood and ability to deal with stress (Hays, 1999; Plante, 1999b).

Embarking on an exercise program is difficult for many people. Exercise is time-consuming, and if you're out of shape, your initial attempts may be discouraging. People who do not get enough exercise cite lack of time, lack of convenience, and lack of enjoyment as their reasons (Jackicic & Gallagher, 2002). To circumvent these problems, it is wise to heed the following advice (Greenberg, 2002; Jackicic & Gallagher, 2002; Phillips, Kiernan, & King, 2001):

1. Select an activity that you find enjoyable.
2. Increase your participation gradually.
3. Exercise regularly without overdoing it.
4. Reinforce yourself for your efforts.

If you choose a competitive sport (such as tennis), try to avoid falling into the competition trap. If you become obsessed with winning, you'll put yourself under pressure and *add* to the stress in your life.

REVIEW of Key Points

13.24 Ellis emphasizes the importance of reappraising stressful events to detect and dispute catastrophic thinking. According to Ellis, emotional distress is often attributable to irrational assumptions that underlie one's thinking.

13.25 Humor may be useful in efforts to redefine stressful situations. In some cases, releasing pent-up emotions may pay off. Talking the anger out may help drain off negative emotions and foster better health. Stress can also be reduced by learning to be more forgiving toward others.

13.26 Relaxation techniques, such as Benson's relaxation response, can reduce the wear and tear of stress. Physical vulnerability may also be reduced by striving to increase one's fitness through healthy eating, sleeping, and exercise.

Key Learning Goals

13.27 Understand important considerations in evaluating health statistics and making health decisions.

Thinking Rationally About Health Statistics and Decisions

With so many conflicting claims about the best ways to prevent or treat diseases, how can anyone ever decide what to do? It seems that every day a report in the media claims that yesterday's health news was wrong. The inconsistency of health news is only part of the problem. We are also overwhelmed by health-related statistics. As mathematics pundit John Allen Paulos (1995, p. 133) puts it, "Health statistics may be bad for our mental health. Inundated by too many of them, we tend to ignore them completely, to accept them blithely, to disbelieve them closemindedly, or simply to misinterpret their significance."

Making personal decisions about health-related issues may not be easy, but it is particularly important to try to think rationally and systematically about such issues. In this Application, we will discuss a few insights that can help you to think critically about statistics on health risks, then we'll briefly outline a systematic approach to thinking through health decisions.

Evaluating Statistics on Health Risks

News reports seem to suggest that there are links between virtually everything people do, touch, and consume and some type of physical illness. For example, media have reported that coffee consumption is related to hypertension, that sleep loss is related to mortality, and that a high-fat diet is related to heart disease. It's enough to send even the most subdued person into a panic. Fortunately, your evaluation of data on health risks can become more sophisticated by considering the following.

Correlation Is No Assurance of Causation. It is not easy to conduct experiments on health risks, so the vast majority of studies linking lifestyle and demographic factors to diseases are correlational studies. Hence, it pays to remember that no causal link may exist between two variables that happen to be correlated. Thus, when you hear that a factor is related to some disease, try to dig a little deeper and find out *why* scientists think this factor is associated with the disease. The suspected causal factor may be something very different from what was measured.

Statistical Significance Is Not Equivalent to Practical Significance. Reports on health statistics often emphasize that the investigators uncovered "statistically significant" findings. Statistically significant findings are results that are not likely to be due to chance fluctuations (see Chapter 2). Statistical significance is a useful concept, but it can sometimes be misleading (Matthey, 1998). Medical studies are often based on rather large samples, because such samples tend to yield more reliable conclusions than small samples. However, when a large sample is used, weak relationships and small differences between groups can turn out to be statistically significant, and these small differences may not have much practical importance. For example, in one study of sodium (salt) intake and cardiovascular disease, which used a sample of over 14,000 participants, He et al. (1999) found a statistically significant link between high sodium intake and the prevalence of hypertension among normal-weight subjects. However, this statistically significant difference was not particularly large. The prevalence of hypertension among subjects with the lowest sodium intake was 19.1% compared to 21.8% for subjects with the highest sodium intake—not exactly a difference worthy of panic.

Base Rates Should Be Considered in Evaluating Probabilities. In evaluating whether a possible risk factor is associated with some disease, people often fail to consider the base rates of these events and draw far-reaching conclusions based on what may be a matter of sheer coincidence. For example, Paulos (1995) discusses how a handful of cases in which cell phone users developed brain cancer led to unfounded allegations that cell phones cause brain cancer.
Brain cancer is a rare disease, striking only about 6 out of 100,000 Americans per year. But given that many millions of Americans use cell phones, one would expect to find thousands upon thousands of new cases of brain cancer annually among cell phone users. Given the small number of reported cases, Paulos playfully concludes that cell phones must prevent brain cancer.

It is also useful to consider base rates in evaluating percentage increases in diseases. If the base rate of a disease is relatively low, a small increase can sound quite large if it is reported as a percentage. For example, in the He et al. (1999) study, the prevalence of diabetes among subjects with the lowest sodium intake was 2.1% compared to 3.8% for subjects with the highest sodium intake. Based on this small but statistically significant difference, one could say (the investigators did not) that high sodium intake was associated with a 81% increase ([3.8 – 2.1] ÷ 2.1) in the prevalence of diabetes, which would be technically accurate, but an exaggerated way of portraying the results.

Thinking Systematically About Health Decisions

Health decisions are oriented toward the future, which means that there are always uncertainties. And such decisions usually involve weighing potential risks and ben-efits. None of these variables is unique to health decisions—uncertainty, risks, and benefits play prominent roles in economic and political decisions as well as in personal decisions. To illustrate, let's apply some basic principles of quantitative reasoning to a treatment decision involving whether to prescribe Ritalin for a boy who has been diagnosed with attention deficit disorder (ADD). Keep in mind that the general principles applied in this example can be used for a wide variety of decisions.

Seek Information to Reduce Uncertainty. Gather information and check it carefully for accuracy, completeness, and the presence or absence of conflicting information. For example, is the diagnosis of ADD correct? Look for conflicting information that does not fit with this diagnosis. For example, if the child can sit and read for a long period of time, maybe the problem is an undetected hearing loss that makes him appear to be hyperactive in some situations. As you consider the additional information, begin quantifying the degree of uncertainty or its "flip side," your degree of confidence that the diagnosis is correct. If you decide that you are not confident about the diagnosis, you may be trying to solve the wrong problem.

Make Risk-Benefit Assessments. What are the risks and benefits of Ritalin? How likely is this child to benefit from Ritalin, and just how much improvement can be expected? If the child is 8 years old and unable to read and is miserable in school and at home, any treatment that could reduce his problems deserves serious consideration. As in the first step, the quantification is at an approximate level.

List Alternative Courses of Action. What are the alternatives to Ritalin? How well do they work? What are the risks associated with the alternatives, including the risk of falling further behind in school? Consider the pros and cons of each alternative. A special diet that sometimes works might be a good first step, along with the decision to start drug therapy if the child does not show improvement over some time period. What are the relative success rates for various types of treatment for children like the one being considered? To answer these questions, you will need to use probability estimates in your decision making.

As you can see from this example, many parts of the problem have been quantified (confidence in the diagnosis, likelihood of improvement, probability of negative outcomes, and so forth). Precise probability values were not used because the actual numbers often are not known. Some of the quantified values reflect value judgments, others reflect likelihoods, and others assess the degree of uncertainty. If you are thinking that the quantification of many unknowns in decision making is a lot of work, you are right. But, it is work worth doing. Whenever important decisions must be made about health, the ability to think with numbers will help you reach a better decision. And yes, that assertion is a virtual certainty.

Table 13.4 Critical Thinking Skills Discussed in This Application

Skill	Description
Understanding the limitations of correlational evidence	The critical thinker understands that a correlation between two variables does not demonstrate that there is a causal link between the variables.
Understanding the limitations of statistical significance	The critical thinker understands that weak relationships can be statistically significant when large samples are used in research.
Utilizing base rates in making predictions and evaluating probabilities	The critical thinker appreciates that the initial proportion of some group or event needs to be considered in weighing probabilities.
Seeking information to reduce uncertainty	The critical thinker understands that gathering more information can often decrease uncertainty, and reduced uncertainty can facilitate better decisions.
Making risk-benefit assessments	The critical thinker is aware that most decisions have risks and benefits that need to be weighed carefully.
Generating and evaluating alternative courses of action	In problem solving and decision making, the critical thinker knows the value of generating as many alternatives as possible and assessing their advantages and disadvantages.

Key Ideas

The Nature of Stress

∎ Stress is a common, everyday event, and even seemingly minor stressors or hassles can be problematic. To a large degree, stress lies in the eye of the beholder, as appraisals of stress are highly subjective.

∎ Major types of stress include frustration, conflict, change, and pressure. Frustration occurs when an obstacle prevents one from attaining some goal. The three principal types of conflict are approach-approach, avoidance-avoidance, and approach-avoidance.

∎ A large number of studies with the SRRS suggest that change is stressful. Although this may be true, it is now clear that the SRRS is a measure of general stress rather than just change-related stress. Two kinds of pressure (to perform and conform) also appear to be stressful.

Responding to Stress

∎ Emotional reactions to stress typically include anger, fear, and sadness, although positive emotions may also occur and may promote resilience. Emotional arousal may interfere with coping. The optimal level of arousal on a task depends on the complexity of the task.

∎ Physiological arousal in response to stress was originally called the fight-or-flight response by Cannon. The fight-or-flight response may be less applicable to women than men. Selye's general adaptation syndrome describes three stages in physiological reactions to stress: alarm, resistance, and exhaustion.

∎ There are two major pathways along which the brain sends signals to the endocrine system in response to stress. Actions along these paths release two sets of hormones, catecholamines and corticosteroids, into the bloodstream. Stress may suppress the process of neurogenesis.

∎ Some coping responses are less than optimal. They include giving up, blaming oneself, and striking out at others with acts of aggression. Indulging oneself is another coping pattern that tends to be of limited value. Defense mechanisms protect against emotional distress through self-deception. Small positive illusions about oneself may sometimes be adaptive.

The Effects of Stress on Psychological Functioning

∎ Common negative effects of stress in terms of psychological functioning include impaired task performance, burnout, and a variety of other psychological problems and disorders. Stress may also have positive effects, stimulating personal growth and the acquisition of new strengths. Resilience may be more common than assumed.

The Effects of Stress on Physical Health

∎ The Type A personality has been implicated as a contributing cause of coronary heart disease, but hostility may be the toxic element of the Type A syndrome. Transient emotional reactions to stressful events and depression have also been identified as cardiovascular risk factors.

∎ Stress may play a role in a variety of diseases because it can temporarily suppress the effectiveness of the immune system and promote inflammation. Although there's little doubt that stress can contribute to the development of physical illness, the link between stress and illness is modest.

Factors Moderating the Impact of Stress

∎ Social support is a key moderator of the relationship between stress and illness; it is associated with better mental and physical health and with reduced mortality. Optimism may lead to more effective coping strategies, and conscientiousness may promote better health habits.

Health-Impairing Behavior

∎ People display many forms of health-impairing behavior. Smokers have much higher mortality rates than nonsmokers because they are more vulnerable to a host of diseases.

∎ Poor nutritional habits have been linked to heart disease, hypertension, and cancer, among other things. Lack of exercise elevates one's risk for cardiovascular diseases, whereas regular exercise is associated with a host of benefits. Alcohol and drug use carry the immediate risk of overdose and elevate the long-term risk of many diseases.

∎ Aspects of behavior also influence one's risk of AIDS. Misconceptions about AIDS are common, and the people who hold these misconceptions tend to fall into polarized camps, either overestimating or underestimating their risk of infection. Health-impairing habits tend to develop gradually and often involve pleasant activities.

Reactions to Illness

∎ Ignoring physical symptoms may result in the delay of needed medical treatment. There are many barriers to effective communication between patients and health care providers. Noncompliance with medical advice is a major problem.

Reflecting on the Chapter's Themes

∎ Two of our integrative themes were prominent in this chapter. First, we saw that behavior and health are influenced by multiple causes. Second, we saw that experience is highly subjective, as stress lies in the eye of the beholder.

PERSONAL APPLICATION Improving Coping and Stress Management

∎ Action-oriented, realistic, constructive coping can be helpful in managing the stress of daily life. Ellis emphasizes the importance of reappraising stressful events to detect and dispute catastrophic thinking. Humor may be useful in efforts to redefine stressful situations.

∎ In some cases, it may pay to release pent-up emotions by expressing them. Forgiving others' transgressions can also reduce stress. Relaxation techniques, such as Benson's relaxation response, can be helpful in stress management. Regular exercise can help make one less vulnerable to the ravages of stress.

CRITICAL THINKING APPLICATION Thinking Rationally About Health Statistics and Decisions

∎ Evaluations of statistics on health risks can be enhanced by remembering that correlation is no assurance of causation, that statistical significance is not equivalent to practical significance, and that base rates need to be considered in assessing probabilities. In trying to think systematically about health decisions, one should seek information to reduce uncertainty, make risk-benefit assessments, and consider alternative courses of action.

Type A personality (p. 551)
Type B personality (p. 551)

Key People

Walter Cannon (p. 542)
Robin DiMatteo (pp. 562–563)
Albert Ellis (pp. 545, 565–566)
Meyer Friedmpan and Ray Rosenman (p. 551)
Thomas Holmes and Richard Rahe (pp. 537–538)
Janice Kiecolt-Glaser (pp. 554–555)
Richard Lazarus (p. 535)
Martin Seligman (p. 557)
Hans Selye (pp. 542–543)
Shelley Taylor (pp. 542, 547)

1. It is the weekend before a major psychology exam on Monday, and Janine is experiencing total panic even though she is thoroughly prepared and aced the previous two psychology exams. Janine's panic illustrates that:
   A. high arousal is optimal on complex tasks.
   B. the appraisal of stress is quite objective.
   C. the appraisal of stress is highly subjective.
   D. her adrenal cortex is malfunctioning.

2. The four principal types of stress are:
   A. frustration, conflict, pressure, and anxiety.
   B. frustration, anger, pressure, and change.
   C. anger, anxiety, depression, and annoyance.
   D. frustration, conflict, pressure, and change.

3. When your boss tells you that a complicated report that you have not yet begun to write must be on her desk by this afternoon, you may experience:
   A. burnout.   C. a double bind.
   B. pressure.   D. catharsis.

4. You want to ask someone for a date, but you are afraid to risk rejection. You are experiencing:
   A. an approach-avoidance conflict.
   B. an avoidance-avoidance conflict.
   C. frustration.
   D. self-imposed pressure.

5. Research suggests that a high level of arousal may be most optimal for the performance of a task when:
   A. the task is complex.
   B. the task is simple.
   C. the rewards are high.
   D. an audience is present.

6. The alarm stage of Hans Selye's general adaptation syndrome is essentially the same as:
   A. the fight-or-flight response.
   B. constructive coping.
   C. catharsis.
   D. secondary appraisal.

7. The brain structure responsible for initiating action along the two major pathways through which the brain sends signals to the endocrine system is the:
   A. hypothalamus.   C. corpus callosum.
   B. thalamus.   D. medulla.

8. You have been doing poorly in your psychology class and are in danger of flunking. Which of the following qualifies as a defense mechanism in response to this situation?
   A. You seek the aid of a tutor.
   B. You decide to withdraw from the class and take it another time.
   C. You deny the reality that you are hopelessly behind in the class, convinced that you will somehow ace the final without seeking help.
   D. You consult with the instructor to see what you can do to pass the class.

9. Physical and emotional exhaustion, cynicism, and lowered self-efficacy attributable to chronic work-related stress is referred to as:
   A. learned helplessness.
   B. burnout.
   C. fallout.
   D. posttraumatic stress disorder.

10. Which personality trait seems to be most strongly related to increased coronary risk?
    A. Type B personality
    B. perfectionism
    C. competitiveness
    D. hostility

11. Many students develop colds and other minor ailments during final exams. This probably happens because:
    A. stress is associated with the release of corticosteroid hormones.
    B. stress is associated with the release of catecholamine hormones.
    C. burnout causes colds.
    D. stress can suppress immune functioning.

12. Research has found that optimists are more likely than pessimists to:
    A. take their time in confronting problems.
    B. identify the negatives before they identify the positives.
    C. engage in action-oriented, problem-focused coping.
    D. blame others for their personal problems.

13. Which of the following has not been found to be a mode of transmission for the HIV virus?
    A. sexual contact among homosexual men
    B. the sharing of needles by intravenous drug users
    C. sexual contact among heterosexuals
    D. sharing food

14. According to Albert Ellis, problematic emotional reactions are caused by:
    A. the fight-or-flight response.
    B. catharsis.
    C. catastrophic thinking.
    D. excessive reliance on defense mechanisms.

15. In evaluating health statistics, it is useful to:
    A. remember that statistical significance is equivalent to practical significance.
    B. remember that correlation is a reliable indicator of causation.
    C. consider base rates in thinking about probabilities.
    D. do all of the above.

Psychological Disorders

"The government of the United States was overthrown more than a year ago! I'm the president of the United States of America and Bob Dylan is vice president!" So said Ed, the author of a prominent book on journalism, who was speaking to a college journalism class, as a guest lecturer. Ed also informed the class that he had killed both John and Robert Kennedy, as well as Charles de Gaulle, the former president of France. He went on to tell the class that all rock music songs were written about him, that he was the greatest karate expert in the universe, and that he had been fighting "space wars" for 2000 years. The students in the class were mystified by Ed's bizarre, disjointed "lecture," but they assumed that he was putting on a show that would eventually lead to a sensible conclusion. However, their perplexed but expectant calm was shattered when Ed pulled a hatchet from the props he had brought with him and hurled the hatchet at the class! Fortunately, he didn't hit anyone, as the hatchet sailed over the students' heads. At that point,
the professor for the class realized that Ed's irrational behavior was not a pretense. The professor evacuated the class quickly while Ed continued to rant and rave about his presidential administration, space wars, vampires, his romances with female rock stars, and his personal harem of 38 "chicks." (Adapted from Pearce, 1974)

Clearly Ed's behavior was abnormal. Even *he* recognized that when he agreed later to be admitted to a mental hospital, signing himself in as the "President of the United States of America." What causes such abnormal behavior? Does Ed have a mental illness, or does he just behave strangely? What is the basis for judging behavior as normal versus abnormal? Are people who have psychological disorders dangerous? How common are such disorders? Can they be cured? These are just a few of the questions that we will address in this chapter as we discuss psychological disorders and their complex causes.

Abnormal Behavior: Myths, Realities, and Controversies

Misconceptions about abnormal behavior are common. We therefore need to clear up some preliminary issues before we describe the various types of disorders. In this section, we will discuss (1) the medical model of abnormal behavior, (2) the criteria of abnormal behavior, (3) stereotypes regarding psychological disorders, (4) the classification of psychological disorders, and (5) the prevalence of such disorders.

The Medical Model Applied to Abnormal Behavior

In Ed's case, there's no question that his behavior was abnormal. But does it make sense to view his

Figure 14.1

Historical conceptions of mental illness. In the Middle Ages people who behaved strangely were sometimes thought to be in league with the devil. The top drawing depicts some of the cruel methods used to extract confessions from suspected witches and warlocks. Some psychological disorders were also thought to be caused by demonic possession. The bottom illustration depicts an exorcism.

unusual and irrational behavior as an illness? This is a controversial question. **The *medical model* proposes that it is useful to think of abnormal behavior as a disease.** This point of view is the basis for many of the terms used to refer to abnormal behavior, including mental *illness,* psychological *disorder,* and psycho*pathology* (*pathology* refers to manifestations of disease). The medical model gradually became the dominant way of thinking about abnormal behavior during the 18th and 19th centuries, and its influence remains strong today.

The medical model clearly represented progress over earlier models of abnormal behavior. Prior to the 18th century, most conceptions of abnormal behavior were based on superstition. People who behaved strangely were thought to be possessed by demons, to be witches in league with the devil, or to be victims of God's punishment. Their disorders were "treated" with chants, rituals, exorcisms, and such. If the people's behavior was seen as threatening, they were candidates for chains, dungeons, torture, and death (see **Figure 14.1**).

The rise of the medical model brought improvements in the treatment of those who exhibited abnormal behavior. As victims of an illness, they were viewed with more sympathy and less hatred and fear. Although living conditions in early asylums were deplorable, gradual progress was made toward more humane care of the mentally ill. It took time, but ineffectual approaches to treatment eventually gave way to scientific investigation of the causes and cures of psychological disorders.

However, in recent decades, some critics have suggested that the medical model may have outlived its usefulness (Boyle, 2007; Kiesler, 1999). A particularly vocal critic has been Thomas Szasz (1974, 1990). He asserts that "strictly speaking, disease or illness can affect only the body; hence there can be no mental illness. . . . Minds can be 'sick' only in the sense that jokes are 'sick' or economies are 'sick'" (1974, p. 267). He further argues that abnormal behavior usually involves a deviation from social norms rather than an illness. He contends that such deviations are "problems in living" rather than medical problems. According to Szasz, the medical model's disease analogy converts moral and social questions about what is acceptable behavior into medical questions.

Although Szasz's criticism of the medical model has some merit, we'll take the position that the disease analogy continues to be useful, although one

should remember that it is *only* an analogy. Medical concepts such as *diagnosis, etiology,* and *prognosis* have proven valuable in the treatment and study of abnormality. ***Diagnosis* involves distinguishing one illness from another. *Etiology* refers to the apparent causation and developmental history of an illness. A *prognosis* is a forecast about the probable course of an illness.** These medically based concepts have widely shared meanings that permit clinicians, researchers, and the public to communicate more effectively in their discussions of abnormal behavior.

Criteria of Abnormal Behavior

If your next-door neighbor scrubs his front porch twice a day and spends virtually all his time cleaning and recleaning his house, is he normal? If your sister-in-law goes to one physician after another seeking treatment for physical ailments that appear imaginary, is she psychologically healthy? How are we to judge what's normal and what's abnormal? More important, who's to do the judging?

These are complex questions. In a sense, *all* people make judgments about normality in that they all express opinions about others' (and perhaps their own) mental health. Of course, formal diagnoses of psychological disorders are made by mental health professionals. In making these diagnoses, clinicians rely on a variety of criteria, the foremost of which are the following:

1. *Deviance.* As Szasz has pointed out, people are often said to have a disorder because their behavior deviates from what their society considers acceptable. What constitutes normality varies somewhat from one culture to another, but all cultures have such norms. When people violate these standards and expectations, they may be labeled mentally ill. For example, *transvestic fetishism* is a sexual disorder in which a man achieves sexual arousal by dressing in women's clothing. This behavior is regarded as disordered because a man who wears a dress, brassiere, and nylons is deviating from our culture's norms.

2. *Maladaptive behavior.* In many cases, people are judged to have a psychological disorder because their everyday adaptive behavior is impaired. This is the key criterion in the diagnosis of substance use (drug) disorders. In and of itself, alcohol and drug use is not all that unusual or deviant. However, when the use of cocaine, for instance, begins to interfere with a person's social or occupational functioning, a substance use disorder exists. In such cases, it is the maladaptive quality of the behavior that makes it disordered.

3. *Personal distress.* Frequently, the diagnosis of a psychological disorder is based on an individual's report of great personal distress. This is usually the criterion met by people who are troubled by depression or anxiety disorders. Depressed people, for instance, may or may not exhibit deviant or maladaptive behavior. Such people are usually labeled as having a disorder when they describe their subjective pain and suffering to friends, relatives, and mental health professionals.

Although two or three criteria may apply in a particular case, people are often viewed as disordered when only one criterion is met. As you may have already noticed, diagnoses of psychological disorders involve *value judgments* about what represents normal or abnormal behavior (Sadler, 2005; Widiger & Sankis, 2000). The criteria of mental illness are not nearly as value-free as the criteria of physical illness. In evaluating physical diseases, people can usually agree that a malfunctioning heart or kidney is pathological, regardless of their personal values. However, judgments about mental illness reflect prevailing cultural values, social trends, and political forces, as well as scientific knowledge (Kutchins & Kirk, 1997; Mechanic, 1999).

Antonyms such as *normal* versus *abnormal* and *mental health* versus *mental illness* imply that people can be divided neatly into two distinct groups: those who are normal and those who are not. In reality, it is often difficult to draw a line that clearly separates normality from abnormality. On occasion, everybody acts in deviant ways, everyone displays some maladaptive behavior, and everyone experiences personal

distress. People are judged to have psychological disorders only when their behavior becomes *extremely* deviant, maladaptive, or distressing. Thus, normality and abnormality exist on a continuum. It's a matter of degree, not an either-or proposition (see Figure 14.2).

Figure 14.2

Normality and abnormality as a continuum. No sharp boundary exists between normal and abnormal behavior. Behavior is normal or abnormal in degree, depending on the extent to which one's behavior is deviant, personally distressing, or maladaptive.

---

concept check 14.1

Applying the Criteria of Abnormal Behavior

Check your understanding of the criteria of abnormal behavior by identifying the criteria met by each of the examples below and checking them off in the table provided. Keep in mind that a specific behavior may meet more than one criterion. The answers are in Appendix A.

Behavioral examples

1. Alan's performance at work has suffered because he has been drinking alcohol to excess. Several co-workers have suggested that he seek help for his problem, but he thinks that they're getting alarmed over nothing. "I just enjoy a good time once in a while," he says.

2. Monica has gone away to college and feels lonely, sad, and dejected. Her grades are fine, and she gets along okay with the other students in the dormitory, but inside she's choked with gloom, hopelessness, and despair.

3. Boris believes that he's Napoleon reborn. He believes that he is destined to lead the U.S. military forces into a great battle to recover California from space aliens.

4. Natasha panics with anxiety whenever she leaves her home. Her problem escalated gradually until she was absent from work so often that she was fired. She hasn't been out of her house in nine months and is deeply troubled by her problem.

Criteria met by each example

	Maladaptive behavior	Deviance	Personal distress
1. Alan	_____	_____	_____
2. Monica	_____	_____	_____
3. Boris	_____	_____	_____
4. Natasha	_____	_____	_____

Stereotypes of Psychological Disorders

We've seen that mental illnesses are not diseases in a strict sense and that judgments of mental health are not value-free. However, still other myths about abnormal behavior need to be exposed as such. Let's examine three stereotypes about psychological disorders that are largely inaccurate:

1. *Psychological disorders are incurable.* Admittedly, there are mentally ill people for whom treatment is largely a failure. However, they are greatly outnumbered by people who do get better, either spontaneously or through formal treatment (Lambert & Ogles, 2004). The vast majority of people who are diagnosed as mentally ill eventually improve and lead normal, productive lives. Even the most severe psychological disorders can be treated successfully.

2. *People with psychological disorders are often violent and dangerous.* Only a modest association has been found between mental illness and violence-prone tendencies (Monahan, 1997; Tardiff, 1999). This stereotype exists because incidents of violence involving the mentally ill tend to command media attention. For example, our opening case history, which described Ed's breakdown and the episode with the hatchet, was written up in a national news magazine. People such as John Hinckley, Jr., whose mental illness led him to attempt an assassination of President Ronald Reagan in 1981, and Seung-Hui Cho, whose mental disorder led him to massacre 32 fellow students at Virginia Tech University, receive enormous publicity. However, these individuals are not representative of the immense number of people who have struggled with psychological disorders.

3. *People with psychological disorders behave in bizarre ways and are very different from normal people.* This is true only in a small minority of cases, usually involving relatively severe disorders. As noted earlier, the line between normal and abnormal behavior can be difficult to draw. At first glance, people with psychological disorders are usually indistinguishable from those without disorders. A classic study by David Rosenhan (1973) showed that even mental health professionals may have difficulty distinguishing normality from abnormality. To study diagnostic accuracy, Rosenhan arranged for a number of normal people to seek admission to mental hospitals. These "pseudopatients" arrived at the hospitals complaining of one false symptom—hearing voices. Except for this single symptom, they acted as they normally would and gave accurate information when interviewed about their personal histories. *All* the pseudopatients were admitted, and the average length of their hospi-

talization was 19 days! As you might imagine, Rosenhan's study evoked quite a controversy about our diagnostic system for mental illness. Let's take a look at how this diagnostic system has evolved.

Psychodiagnosis: The Classification of Disorders

Lumping all psychological disorders together would make it extremely difficult to understand them better. A sound taxonomy of mental disorders can facilitate empirical research and enhance communication among scientists and clinicians (First, 2003; Zimmerman & Spitzer, 2005). Thus, a great deal of effort has been invested in devising an elaborate system for classifying psychological disorders (see **Figure 14.3** on the next page).

Guidelines for psychodiagnosis were extremely vague and informal prior to 1952 when the American Psychiatric Association unveiled its *Diagnostic and Statistical Manual of Mental Disorders* (Nathan & Langenbucher, 2003). This classification scheme described about 100 disorders. Revisions intended to improve the system were incorporated into the second edition (DSM-II) published in 1968, but the diagnostic guidelines were still pretty sketchy. However, the third edition (DSM-III), published in 1980, represented a major advance, as the diagnostic criteria were made much more explicit, concrete, and detailed to facilitate more consistent diagnoses across clinicians (Blacker & Tsuang, 1999). The current, fourth edition (DSM-IV), which was released in 1994, and revised slightly in 2000, made use of intervening research to refine the criteria introduced in DSM-III. Each revision of the DSM system has expanded the list of disorders covered. The current version describes about three times as many types of psychological disorders as DSM-I (Houts, 2002).

The publication of DSM-III in 1980 introduced a new multiaxial system of classification, which asks for judgments about individuals on five separate dimensions, or "axes." **Figure 14.3** provides an overview of the axes. The diagnoses of disorders are made on Axes I and II. Clinicians record most types of disorders on Axis I. They use Axis II to list long-running personality disorders or mental retardation. People may receive diagnoses on both Axes I and II. The remaining axes are used to record supplemental information. A patient's physical disorders are listed on Axis III (General Medical Conditions). On Axis IV (Psychosocial and Environmental Problems), the clinician makes notations regarding the types of stress experienced by the individual in the past year. On Axis V (Global Assessment of Functioning), estimates are made of the individual's cur-

rent level of adaptive functioning (in social and occupational behavior, viewed as a whole) and of the individual's highest level of functioning in the past year. **Figure 14.4** on page 581 shows an example of a multiaxial evaluation. Most theorists agree that the multiaxial system is a step in the right direction because it recognizes the importance of information besides a traditional diagnostic label.

Work is currently underway to formulate the next edition (DSM-V) of the diagnostic system (e.g., Banzato, 2004; Spitzer, First, & Wakefield, 2007; Widiger & Simonsen, 2005), which is tentatively scheduled for publication in 2011. Clinical researchers are collecting data, holding conferences, and formulating arguments about whether various syndromes should be added, eliminated, redefined, or renamed. Should complicated grief reactions become a standard diagnostic option (Lichtenthal, Cruess, & Prigerson, 2004)? Should the diagnostic system use the term drug *dependence* or drug *addiction* (O'Brien, Volkow, & Li, 2006)? Should pathological gambling be lumped with impulse-control disorders or addictive disorders (Potenza, 2006)? Should the category of somatoform disorders (see pp. 586–588) be eliminated (Fava et al., 2007)? Should Internet addiction be added to the official list of disorders (Sandoz, 2004)? Vigorous debates about issues such as these will occupy clinical researchers in the upcoming years, and DSM-V may look somewhat different from its predecessors.

The Prevalence of Psychological Disorders

How common are psychological disorders? What percentage of the population is afflicted with mental illness? Is it 10%? Perhaps 25%? Could the figure range as high as 40% or 50%?

Such estimates fall in the domain of *epidemiology—the study of the distribution of mental or physical disorders in a population.* The 1980s and 1990s brought major advances in psychiatric epidemiology, as a number of large-scale investigations provided a huge, new database on the distribution of mental disorders (Murphy, Tohen, & Tsuang, 1999). In epidemiology, *prevalence* refers to the percentage of a population that exhibit a disorder during a specified time period. In the case of mental disorders, the most interesting data are the estimates of *lifetime prevalence,* the percentage of people who endure a specific disorder at any time in their lives.

Studies published in the 1980s and early 1990s found psychological disorders in roughly *one-third* of the population (Regier & Kaelber, 1995; Robins, Locke, & Regier, 1991). Subsequent research, which focused on a somewhat younger sample (ages 18–54 instead

Axis I
Clinical Syndromes

1. **Disorders usually first diagnosed in infancy, childhood, or adolescence**
   This category includes disorders that arise before adolescence, such as attention deficit disorders, autism, enuresis, and stuttering.

2. **Organic mental disorders**
   These disorders are temporary or permanent dysfunctions of brain tissue caused by diseases or chemicals. Examples are delirium, dementia, and amnesia.

3. **Substance-related disorders**
   This category refers to the maladaptive use of drugs and alcohol. This category requires an abnormal pattern of use, as with alcohol abuse and cocaine dependence.

4. **Schizophrenia and other psychotic disorders**
   The schizophrenias are characterized by psychotic symptoms (for example, grossly disorganized behavior, delusions, and hallucinations) and by over six months of behavioral deterioration. This category also includes delusional disorder and schizoaffective disorder.

5. **Mood disorders**
   The cardinal feature is emotional disturbance. These disorders include major depression, bipolar disorder, dysthymic disorder, and cyclothymic disorder.

6. **Anxiety disorders**
   These disorders are characterized by physiological signs of anxiety (for example, palpitations) and subjective feelings of tension, apprehension, or fear. Anxiety may be acute and focused (panic disorder) or continual and diffuse (generalized anxiety disorder).

7. **Somatoform disorders**
   These disorders are dominated by somatic symptoms that resemble physical illnesses. These symptoms cannot be fully accounted for by organic damage. This category includes somatization and conversion disorders and hypochondriasis.

8. **Dissociative disorders**
   These disorders all feature a sudden, temporary alteration or dysfunction of memory, consciousness, and identity, as in dissociative amnesia and dissociative identity disorder.

9. **Sexual and gender-identity disorders**
   There are three basic types of disorders in this category: gender identity disorders (discomfort with identity as male or female), paraphilias (preference for unusual acts to achieve sexual arousal), and sexual dysfunctions (impairments in sexual functioning).

10. **Eating Disorders**
    Eating disorders are severe disturbances in eating behavior characterized by preoccupation with weight concerns and unhealthy efforts to control weight. Examples include anorexia nervosa and bulimia nervosa.

Axis II
Personality Disorders or Mental Retardation

Personality disorders are longstanding patterns of extreme, inflexible personality traits that are deviant or maladaptive and lead to impaired functioning or subjective distress. *Mental retardation* refers to subnormal general mental ability accompanied by deficiencies in adaptive skills, originating before age 18.

Axis III
General Medical Conditions

Physical disorders or conditions are recorded on this axis. Examples include diabetes, arthritis, and hemophilia.

Axis IV
Psychosocial and Environmental Problems

Axis IV is for reporting psychosocial and environmental problems that may affect the diagnosis, treatment, and prognosis of mental disorders (Axes I and II). A psychosocial or environmental problem may be a negative life event, an environmental difficulty or deficiency, a familial or other interpersonal stress, an inadequacy of social support or personal resources, or another problem that describes the context in which a person's difficulties have developed.

Axis V
Global Assessment of Functioning (GAF) Scale

Code	Symptoms
100	Superior functioning in a wide range of activities
90	Absent or minimal symptoms, good functioning in all areas
80	Symptoms transient and expectable reactions to psychosocial stressors
70	Some mild symptoms or some difficulty in social, occupational, or school functioning, but generally functioning pretty well
60	Moderate symptoms or difficulty in social, occupational, or school functioning
50	Serious symptoms or impairment in social, occupational, or school functioning
40	Some impairment in reality testing or communication or major impairment in family relations, judgment, thinking, or mood
30	Behavior considerably influenced by delusions or hallucinations, serious impairment in communication or judgment, or inability to function in almost all areas
20	Some danger of hurting self or others, occasional failure to maintain minimal personal hygiene, or gross impairment in communication
10	Persistent danger of severely hurting self or others
1	

of over age 18), suggested that about 44% of the adult population will struggle with some sort of psychological disorder at some point in their lives (Kessler & Zhao, 1999; Regier & Burke, 2000). The most recent large-scale epidemiological study estimated the lifetime risk of a psychiatric disorder to be 51% (Kessler et al., 2005a). Obviously, all these figures are *estimates* that depend to some extent on the sampling methods and assessment techniques used (Wakefield, 1999b). The progressively higher estimates in recent years have begun to generate some controversy in the field. Some experts believe that recent estimates are

A DSM multiaxial evaluation (patient 49-year-old male)	
Axis I	Major depressive disorder Cocaine abuse
Axis II	Borderline personality disorder (provisional, rule out dependent personality disorder)
Axis III	Hypertension
Axis IV	Psychosocial stressors: recent divorce, permitted to see his children only infrequently, job is in jeopardy
Axis V	Current global assessment of functioning (GAF): 46

Figure 14.4

Example of a multiaxial evaluation. A multiaxial evaluation for a depressed man with a cocaine problem might look like this.

Figure 14.5

Lifetime prevalence of psychological disorders. The estimated percentage of people who have, at any time in their life, suffered from one of four types of psychological disorders or from a disorder of any kind (top bar) is shown here. Prevalence estimates vary somewhat from one study to the next, depending on the exact methods used in sampling and assessment. The estimates shown here are based on pooling data from Wave 1 and 2 of the Epidemiological Catchment Area studies and the National Comorbidity Study, as summarized by Regier and Burke (2000) and Dew, Bromet, and Switzer (2000). These studies, which collectively evaluated over 28,000 subjects, provide the best data to date on the prevalence of mental illness in the United States.

implausibly high and that they may trivialize psychiatric diagnoses (Wakefield & Spitzer, 2002). The debate centers on where to draw the line between normal difficulties in functioning and full-fledged mental illness—that is, when symptoms qualify as a disease (Regier, Narrow, & Rae, 2004).

In any event, whether one goes with conservative or liberal estimates, the prevalence of psychological disorders is quite a bit higher than most people assume. The data that yielded the 44% estimate of total lifetime prevalence are summarized in **Figure 14.5**, which shows prevalence estimates for the most common classes of disorders. As you can see, the most common types of psychological disorders are (1) substance (alcohol and drug) use disorders, (2) anxiety disorders, and (3) mood disorders.

The high prevalence of psychological disorders means that the economic costs of mental illness in modern societies are enormous. The annual cost of treating psychiatric illness in the United States was estimated to be about $150 billion in a 2003 report (New Freedom Commission on Mental Health, 2003). Another study estimated that more than 1.3 billion days of role performance (being able to go to work, function as a homemaker, and so forth) are lost each year in the U.S. to mental disorders (Merikangas et al., 2007). To put this exorbitant number in perspective, psychological disorders cause about three times as many disability days as cardiovascular diseases and vastly more than cancer. And there is no way to put a price on the extraordinary anguish suffered by the families of the mentally ill. Thus, the socioeconomic costs of psychological disorders are staggering.

We are now ready to start examining the specific types of psychological disorders. Obviously, we cannot cover all of the disorders listed in DSM-IV. However, we will introduce most of the major categories of disorders to give you an overview of the many forms abnormal behavior takes (see Chapter 5 for a discussion of substance abuse). In discussing each set of disorders, we will begin with brief descriptions of the specific syndromes or subtypes that fall in the category. Then we'll focus on the *etiology* of the disorders in that category.

REVIEW of Key Points

14.1 The medical model assumes that it is useful to view abnormal behavior as a disease. This view has been criticized on the grounds that it turns questions about deviance into medical questions, but the model has proven useful. Three criteria are used in deciding whether people suffer from psychological disorders: deviance, personal distress, and maladaptive behavior. Judgments about abnormality reflect cultural values. Often it is difficult to clearly draw a line between normality and abnormality.

14.2 Contrary to popular stereotypes, people with psychological disorders are not particularly bizarre or dangerous, and even the most severe disorders are treatable. Research by David Rosenhan showed that pseudopatients were routinely admitted to mental hospitals, where staff were unable to detect the patients' normalcy. His study showed that the distinction between normality and abnormality is not clear-cut.

14.3 Originally introduced in 1952, the DSM is the official psychodiagnostic classification system in the United States. Since DSM-III, the system has asked for information about patients on five axes, or dimensions. The current version is DSM-IV, but work is under way on DSM-V.

14.4 It is difficult to obtain good data on the prevalence of psychological disorders. Nonetheless, it is clear that they are more common than widely believed. Recent studies suggest that 44% of the population will struggle with a disorder over the course of their lives. The most common types of disorders are substance use, anxiety, and mood disorders.

Key Learning Goals

14.5 Identify five anxiety disorders and the symptoms associated with each.

14.6 Discuss the role of biological factors and conditioning in the etiology of anxiety disorders.

14.7 Explain how cognitive factors and stress can contribute to the development of anxiety disorders.

Anxiety Disorders

SIM 9

Everyone experiences anxiety from time to time. It is a natural and common reaction to many of life's difficulties. For some people, however, anxiety becomes a chronic problem. These people experience high levels of anxiety with disturbing regularity. *Anxiety disorders are a class of disorders marked by feelings of excessive apprehension and anxiety.* There are five principal types of anxiety disorders: generalized anxiety disorder, phobic disorder, panic disorder, obsessive-compulsive disorder, and posttraumatic stress disorder. They are not mutually exclusive, as many people who develop one anxiety syndrome often suffer from another at some point in their lives (Merikangas, 2005). Studies suggest that anxiety disorders are quite common, occurring in roughly 19% of the population (Dew, Bromet, & Switzer, 2000; Regier & Burke, 2000).

Generalized Anxiety Disorder

11a

Generalized anxiety disorder is marked by a chronic, high level of anxiety that is not tied to any specific threat. People with this disorder worry constantly about yesterday's mistakes and tomorrow's problems. They worry about minor matters related to family, finances, work, and personal illness. They hope that their worrying will help to ward off negative events (Beidel & Stipelman, 2007), but they nonetheless worry about how much they worry (Barlow et al., 2003). They often dread making decisions and brood over them endlessly. Their anxiety is commonly accompanied by physical symptoms, such as trembling, muscle tension, diarrhea, dizziness, faintness, sweating, and heart palpitations. Generalized anxiety disorder tends to have a gradual onset, has a lifetime prevalence of about 5%, and is seen more frequently in females than males (Brown, 1999; Merikangas, 2005).

Phobic Disorder

11a

In a phobic disorder, an individual's troublesome anxiety has a specific focus. **A *phobic disorder* is marked by a persistent and irrational fear of an object or situation that presents no realistic danger.** Although mild phobias are extremely common, people are said to have a phobic disorder only when their fears seriously interfere with their everyday behavior. Phobic reactions tend to be accompanied by physical symptoms of anxiety, such as trembling and palpitations (Rapee & Barlow, 2001). The following case provides an example of a phobic disorder:

Hilda is 32 years of age and has a rather unusual fear. She is terrified of snow. She cannot go outside in the snow. She cannot even stand to see snow or hear about it on the weather report. Her phobia severely constricts her day-to-day behavior. Probing in therapy revealed that her phobia was caused by a traumatic experience at age 11. Playing at a ski lodge, she was buried briefly by a small avalanche of snow. She had no recollection of this experience until it was recovered in therapy. (Adapted from Laughlin, 1967, p. 227)

As Hilda's unusual snow phobia illustrates, people can develop phobic responses to virtually anything. Nonetheless, certain types of phobias are more common than others. Particularly common are acrophobia (fear of heights), claustrophobia (fear of small, enclosed places), brontophobia (fear of storms), hydrophobia (fear of water), and various animal and insect phobias (Antony & McCabe, 2003). People troubled by phobias typically realize that their fears are irrational, but they still are unable to calm themselves when confronted by a phobic object. Among many of them, even *imagining* a phobic object or situation can trigger great anxiety (Thorpe & Salkovskis, 1995).

Panic Disorder and Agoraphobia

11a

A *panic disorder* is characterized by recurrent attacks of overwhelming anxiety that usually occur suddenly and unexpectedly. These paralyzing panic attacks are accompanied by physical symptoms of anxiety. After a number of panic attacks, victims often become apprehensive, wondering when their next panic will occur. Their concern about exhibiting panic in public may escalate to the point where they are afraid to leave home. This creates a condition called *agoraphobia,* which is a common complication of panic disorders.

Agoraphobia is a fear of going out to public places (its literal meaning is "fear of the marketplace or open places"). Because of this fear, some people become prisoners confined to their homes, although many will venture out if accompanied by a trusted companion (Hollander & Simeon, 2003). As its name
© Sidney Harris/ScienceCartoonsPlus.com

suggests, agoraphobia has traditionally been viewed as a phobic disorder. However, more recent evidence suggests that agoraphobia is mainly a complication of panic disorder. About two-thirds of people who are diagnosed with panic disorder are female (Horwath & Weissman, 2000). The onset of panic disorder typically occurs during late adolescence or early adulthood (Pine & McClure, 2005).

Obsessive-Compulsive Disorder

PsykTrek 11a

Obsessions are *thoughts* that repeatedly intrude on one's consciousness in a distressing way. Compulsions are *actions* that one feels forced to carry out. Thus, **an *obsessive-compulsive disorder* (OCD) is marked by persistent, uncontrollable intrusions of unwanted thoughts (obsessions) and urges to engage in senseless rituals (compulsions).** To illustrate, let's examine the bizarre behavior of a man once reputed to be the wealthiest person in the world:

The famous industrialist Howard Hughes was obsessed with the possibility of being contaminated by germs. This led him to devise extraordinary rituals to minimize the possibility of such contamination. He would spend hours methodically cleaning a single telephone. He once wrote a three-page memo instructing assistants on exactly how to open cans of fruit for him. The following is just a small portion of the instructions that Hughes provided for a driver who delivered films to his bungalow. "Get out of the car on the traffic side. Do not at any time be on the side of the car between the car and the curb. . . . Carry only one can of film at a time. Step over

the gutter opposite the place where the sidewalk dead-ends into the curb from a point as far out into the center of the road as possible. Do not ever walk on the grass at all, also do not step into the gutter at all. Walk to the bungalow keeping as near to the center of the sidewalk as possible." (Adapted from Barlett & Steele, 1979, pp. 227–237)

Obsessions often center on inflicting harm on others, personal failures, suicide, or sexual acts. People troubled by obsessions may feel that they have lost control of their mind. Compulsions usually involve stereotyped rituals that temporarily relieve anxiety. Common examples include constant handwashing; repetitive cleaning of things that are already clean; endless rechecking of locks, faucets, and such; and excessive arranging, counting, and hoarding of things (Pato, Eisen, & Phillips, 2003). Specific types of obsessions tend to be associated with specific types of compulsions. For example, obsessions about contamination tend to be paired with cleaning compulsions, and obsessions about symmetry tend to be paired with ordering and arranging compulsions (Leckman et al., 1997).

Although many of us can be compulsive at times, full-fledged obsessive-compulsive disorders occur in roughly 2.5% of the population (Turner et al., 2001). The typical age of onset for OCD is late adolescence,

As a young man (shown in the photo), Howard Hughes was a handsome, dashing daredevil pilot and movie producer who appeared to be reasonably well adjusted. However, as the years went by, his behavior gradually became more and more maladaptive, as obsessions and compulsions came to dominate his life. In his later years (shown in the drawing), he spent most of his time in darkened rooms, naked, unkempt, and dirty, following bizarre rituals to alleviate his anxieties. (The drawing was done by an NBC artist and was based on descriptions from men who had seen Hughes.)

with most cases (75%) emerging before the age of 30 (Kessler et al., 2005a). OCD can be a particularly severe disorder, as it is often associated with serious social and occupational impairments (Torres et al., 2006).

Posttraumatic Stress Disorder

Posttraumatic stress disorder (PTSD) involves enduring psychological disturbance attributed to the experience of a major traumatic event. PTSD was first recognized as a disorder in the 1970s in the aftermath of the Vietnam war, when a great many veterans were traumatized by their combat experiences. Research eventually showed that PTSD can be caused by a variety of traumatic events besides harrowing war experiences. For example, PTSD is often seen after a rape or assault, a severe automobile accident, a natural disaster, or the witnessing of someone's death (Koren, Arnon, & Klein, 1999; Stein et al., 1997; Vernberg et al., 1996). Unfortunately, traumatic experiences such as these appear to be much more common than widely assumed. Research suggests that 7%–8% of people have suffered from PTSD at some point in their lives, with prevalence higher among women (10%) than men (5%) (Ozer et al., 2003). Currently, there is great concern about the number of military returnees from the Afghanistan and Iraq wars who will develop PTSD (Friedman, 2006). Similar to the experiences of Vietnam veterans, the preliminary data suggest that these troops are showing greatly elevated rates of PTSD (Hoge et al., 2007). Common symptoms in PTSD include reexperiencing the traumatic event in the form of nightmares and flashbacks, emotional numbing, alienation, problems in social relations, an increased sense of vulnerability, and elevated arousal, anxiety, anger, and guilt (Flannery, 1999; Shalev, 2001).

A variety of factors are predictors of individuals' risk for PTSD (McNally, 1999; Keane, Marshall, & Taft, 2006; Norris et al., 2001). As you might expect, increased vulnerability is associated with greater personal injuries and losses, greater intensity of exposure to the traumatic event, and more exposure to the grotesque aftermath of the event. One key predictor of vulnerability that emerged in a recent review of the relevant research is the *intensity of one's reaction at the time of the traumatic event* (Ozer et al., 2003). Individuals who have especially intense emotional reactions during or immediately after the traumatic event go on to show elevated vulnerability to PTSD. Vulnerability seems to be greatest among people whose reactions are so intense that they report dissociative experiences (a sense that things are not real, that time is stretching out, that one is watching oneself in a movie).

Etiology of Anxiety Disorders

11a

Like most psychological disorders, anxiety disorders develop out of complicated interactions among a variety of biological and psychological factors.

Biological Factors

11a

In studies that assess the impact of heredity on psychological disorders, investigators look at *concordance rates*. **A *concordance rate* indicates the percentage of twin pairs or other pairs of relatives who exhibit the same disorder.** If relatives who share more genetic similarity show higher concordance rates than relatives who share less genetic overlap, this finding supports the genetic hypothesis. The results of both *twin studies* (see **Figure 14.6**) and *family studies* (see Chapter 3 for discussions of both methods) suggest that there is a moderate genetic predisposition to anxiety disorders (Hettema, Neale, & Kendler, 2001; McMahon & Kassem, 2005). These findings are consistent with the idea that inherited differences in temperament might make some people more vulnerable than others to anxiety disorders. As we discussed in Chapter 11, Jerome Kagan and his colleagues (1992) have found that about 15%–20% of infants display an *inhibited temperament,* characterized by shyness, timidity, and wariness, which appears to have a strong genetic basis. Research suggests that this temperament is a risk factor for the development of anxiety disorders (Coles, Schofield, & Pietrefesa, 2006).

Another line of research suggests that *anxiety sensitivity* may make people vulnerable to anxiety disorders (McWilliams et al., 2007; Reiss, 1991; Schmidt, Zvolensky, & Maner, 2006). According to this notion, some people are highly sensitive to the internal physiological symptoms of anxiety and are prone to overreact with fear when they experience these symptoms. Anxiety sensitivity may fuel an inflationary spiral in which anxiety breeds more anxiety, which eventually spins out of control in the form of an anxiety disorder.

Recent evidence suggests that a link may exist between anxiety disorders and neurochemical activity in the brain. As you learned in Chapter 3, *neurotransmitters* are chemicals that carry signals from one neuron to another. Therapeutic drugs (such as Valium) that reduce excessive anxiety appear to alter neurotransmitter activity at GABA synapses. This finding and other lines of evidence suggest that disturbances in the neural circuits using GABA may play a role in some types of anxiety disorders (Skol-

nick, 2003). Abnormalities in neural circuits using serotonin have been implicated in PTSD and panic and obsessive-compulsive disorders (Stein & Hugo, 2004). Thus, scientists are beginning to unravel the neurochemical bases for anxiety disorders.

Conditioning and Learning   11a

Many anxiety responses may be *acquired through classical conditioning and maintained through operant conditioning* (see Chapter 6). According to Mowrer (1947), an originally neutral stimulus (the snow in Hilda's case, for instance) may be paired with a frightening event (the avalanche) so that it becomes a conditioned stimulus eliciting anxiety (see **Figure 14.7a**). Once a fear is acquired through classical conditioning, the person may start avoiding the anxiety-producing stimulus. The avoidance response is negatively reinforced because it is followed by a reduction in anxiety. This process involves operant conditioning (see **Figure 14.7b**). Thus, separate conditioning processes may create and then sustain specific anxiety responses (Levis, 1989). Consistent with this view, studies find that a substantial portion of people suffering from phobias can identify a traumatic conditioning experience that probably contributed to their anxiety disorder (Antony & McCabe, 2003; Mineka & Zinbarg, 2006).

The tendency to develop phobias of certain types of objects and situations may be explained by Martin Seligman's (1971) concept of *preparedness*. He suggests that people are biologically prepared by their evolutionary history to acquire some fears much more easily than others. His theory would explain why people develop phobias of ancient sources of threat (such as snakes and spiders) much more readily than modern sources of threat (such as electrical outlets or hot irons). As we noted in Chapter 6, Arne Öhman and Susan Mineka (2001) have updated the notion of preparedness, which they call an *evolved module for fear learning*. They maintain that this evolved module is automatically activated by stimuli related to past survival threats in evolutionary history and that it is relatively resistant to intentional efforts to suppress the resulting fears. Consistent with this view, phobic stimuli associated with evolutionary threats tend to produce more rapid conditioning of fears and stronger fear responses (Mineka & Öhman, 2002).

Critics note a number of problems with conditioning models of phobias (Rachman, 1990). For instance, many people with phobias cannot recall or identify a traumatic conditioning experience that led to their phobia. Conversely, many people endure extremely traumatic experiences that should create
a phobia but do not. To provide better explanations for these complexities, conditioning models of anxiety disorders are currently being revised to include a larger role for cognitive factors (de Jong & Merckelbach, 2000), much like conditioning theories in general, as we saw in Chapter 6.

Cognitive Factors   11a

Cognitive theorists maintain that certain styles of thinking make some people particularly vulnerable to anxiety disorders (Craske & Waters, 2005). According to these theorists, some people are more likely to suffer from problems with anxiety because they tend to (a) misinterpret harmless situations as threatening, (b) focus excessive attention on perceived threats, and (c) selectively recall information that seems threatening (Beck, 1997; McNally, 1994, 1996). In one intriguing test of the cognitive view, anxious and nonanxious subjects were asked to read 32 sentences that could be interpreted in either a threatening or a nonthreatening manner (Eysenck et al., 1991). For instance, one such sentence was "The doctor examined little Emma's growth," which could mean that the doctor checked her height or the growth of a tumor. As **Figure 14.8** on the next page shows, the anxious participants interpreted the sentences in a threatening way more often than the

Figure 14.6

Twin studies of anxiety disorders. The concordance rate for anxiety disorders in identical twins is higher than that for fraternal twins, who share less genetic overlap. These results suggest that there is a genetic predisposition to anxiety disorders. (Data based on Noyes et al., 1987; Slater & Shields, 1969; Torgersen, 1979, 1983)

(a) Classical conditioning: Acquisition of phobic fear
(b) Operant conditioning: Maintenance of phobic fear (negative reinforcement)
Figure 14.7

Conditioning as an explanation for phobias. **(a)** Many phobias appear to be acquired through classical conditioning when a neutral stimulus is paired with an anxiety-arousing stimulus. **(b)** Once acquired, a phobia may be maintained through operant conditioning. Avoidance of the phobic stimulus reduces anxiety, resulting in negative reinforcement.

Figure 14.8

Cognitive factors in anxiety disorders. Eysenck and his colleagues (1991) compared how subjects with anxiety problems and nonanxious subjects tended to interpret sentences that could be viewed as threatening or nonthreatening. Consistent with cognitive models of anxiety disorders, anxious subjects were more likely to interpret the sentences in a threatening light.

Threatening interpretations endorsed (%)

Figure 14.9

Stress and panic disorder. Faravelli and Pallanti (1989) assessed the amount of stress experienced during the 12 months before the onset of panic disorder in a group of 64 patients with this disorder and in a control group drawn from hospital employees and their friends. As you can see, a dramatic increase occurred in stress in the month prior to the onset of the patients' panic disorders. These data suggest that stress may contribute to the development of panic disorders.

Months prior to onset of panic disorder

in every corner of their lives (Aikens & Craske, 2001; Riskind, 2005).

Stress

Finally, studies have supported the long-held suspicion that anxiety disorders can be stress-related (Beidel & Stipelman, 2007; Sandin et al., 2004). For instance, Faravelli and Pallanti (1989) found that patients with panic disorder had experienced a dramatic increase in stress in the month prior to the onset of their disorder (see **Figure 14.9**). In another study, Brown et al. (1998) found an association between stress and the development of social phobia. Thus, there is reason to believe that high stress often helps to precipitate the onset of anxiety disorders.

REVIEW of Key Points

14.5 Generalized anxiety disorder is marked by chronic, high anxiety, whereas phobic disorder involves irrational fears of specific objects or situations. Panic disorder is marked by recurrent panic attacks and agoraphobia. Obsessive-compulsive disorder is dominated by intrusions of unwanted thoughts and urges, whereas posttraumatic stress disorder consists of disturbance due to the experience of a major traumatic event.

14.6 Twin studies suggest that there is a weak genetic predisposition to anxiety disorders. These disorders may be more likely in people who are especially sensitive to the physiological symptoms of anxiety. Abnormalities in neurotransmitter activity at GABA synapses or serotonin synapses may also play a role. Many anxiety responses, especially phobias, may be caused by classical conditioning and maintained by operant conditioning, with preparedness influencing which phobias condition most readily.

14.7 Cognitive theorists maintain that certain styles of thinking—especially a tendency to overinterpret harmless situations as threatening—make some people more vulnerable to anxiety disorders. Stress may also predispose people to anxiety disorders.

nonanxious participants did. Thus, consistent with our theme that human experience is highly subjective, the cognitive view holds that some people are prone to anxiety disorders because they see threat

Somatoform Disorders

Key Learning Goals

14.8 Distinguish among three somatoform disorders.

14.9 Analyze how personality, cognitive factors, and the sick role contribute to somatoform disorders.

Chances are, you have met people who always seem to be complaining about aches, pains, and physical maladies of doubtful authenticity. You may have thought to yourself, "It's all in his head" and concluded that the person exhibited a "psychosomatic" condition. However, as we discussed in Chapter 13, the term *psychosomatic* has been widely misused. *Psychosomatic diseases* involve *genuine* physical ailments caused in part by psychological factors, especially reactions to stress. These diseases, which include mal-

adies such as ulcers, asthma, and high blood pressure, are not imagined ailments. They are recorded on the DSM axis for physical problems (Axis III). When physical illness appears *largely* psychological in origin, we are dealing with somatoform disorders, which are recorded on Axis I. *Somatoform disorders are physical ailments that cannot be fully explained by organic conditions and are largely due to psychological factors.* Although their symptoms are more imaginary than real, victims of somato-

form disorders are *not* simply faking illness. Deliberate feigning of illness for personal gain is another matter altogether, called *malingering*.

People with somatoform disorders typically seek treatment from physicians practicing neurology, internal medicine, or family medicine, instead of from psychologists or psychiatrists. Making accurate diagnoses of somatoform disorders can be difficult, because the causes of physical ailments are sometimes hard to identify. In some cases, somatoform disorders are misdiagnosed when a genuine organic cause for a person's physical symptoms goes undetected in spite of extensive medical examinations and tests (Yutzy, 2003). Diagnostic ambiguities such as these have led some theorists to argue that the category of somatoform disorders should be eliminated in DSM-V (Mayou et al., 2005), but other theorists have expressed vigorous disagreement (Rief, Henningsen, & Hiller, 2006).

Subtypes and Symptoms

We will discuss three specific types of somatoform disorders: somatization disorder, conversion disorder, and hypochondriasis. Diagnostic difficulties make it hard to obtain sound data on the prevalence of somatoform disorders (Bouman, Eifert, & Lejuez, 1999).

Somatization Disorder
Individuals with somatization disorder are often said to "cling to ill health." **A *somatization disorder* is marked by a history of diverse physical complaints that appear to be psychological in origin.** Somatization disorder occurs mostly in women (Guggenheim, 2000) and often coexists with depression and anxiety disorders (Gureje et al., 1997). Victims report an endless succession of minor physical ailments that seem to wax and wane in response to the stress in their lives (Servan-Schreiber, Kolb, & Tabas, 1999). They usually have a long and complicated history of medical treatment from many doctors. The distinguishing feature of this disorder is the diversity of the victims' physical complaints. Over the years, they report a mixed bag of cardiovascular, gastrointestinal, pulmonary, neurological, and genitourinary symptoms. The unlikely nature of such a smorgasbord of symptoms occurring together often alerts a physician to the possible psychological basis for the patient's problems. However, somatization patients are typically very resistant to the suggestion that their symptoms might be the result of psychological distress (Hollifield, 2005).

Conversion Disorder
***Conversion disorder* is characterized by a significant loss of physical function (with no apparent organic basis), usually in a single organ system.** Common symptoms include partial or complete loss of vision, partial or complete loss of hearing, partial paralysis, severe laryngitis or mutism, and loss of feeling or function in limbs. People with conversion disorder are usually troubled by more severe ailments than people with somatization disorder. In some cases of conversion disorder, telltale clues reveal the psychological origins of the illness because the patient's symptoms are not consistent with medical knowledge about their apparent disease. For instance, the loss of feeling in one hand that is seen in "glove anesthesia" is inconsistent with the known facts of neurological organization (see Figure 14.10). Conversion disorders tend to have an acute onset triggered by stress (Kirmayer & Looper, 2007).

Hypochondriasis
Hypochondriacs constantly monitor their physical condition, looking for signs of illness. Any tiny alteration from their physical norm leads them to conclude that they have contracted a disease. ***Hypochondriasis* (more widely known as hypochondria) is characterized by excessive preoccupation with health concerns and incessant worry about developing physical illnesses.** When hypochondriacs are assured by their physician that they do not have any real illness, they often are skeptical and disbelieving (Starcevic, 2001). They frequently assume that the physician must be incompetent, and they go shopping for another doctor. Hypochondriacs don't subjectively suffer from physical distress so much as they *overinterpret* every conceivable sign of illness. Hypochondria frequently appears alongside other

(a)   (b)

Figure 14.10
Glove anesthesia. In conversion disorders, the physical complaints are sometimes inconsistent with the known facts of physiology. For instance, given the patterns of nerve distribution in the arm shown in (a), it is impossible that a loss of feeling in the hand exclusively, as shown in (b), has a physical cause, indicating that the patient's problem is psychological in origin.

"Assuming I am a hypochondriac, couldn't that condition be brought on by a brain tumor?"

psychological disorders, especially anxiety disorders and depression (Iezzi, Duckworth, & Adams, 2001). For example, Howard Hughes's obsessive-compulsive disorder was coupled with profound hypochondria.

Etiology of Somatoform Disorders

Inherited aspects of physiological functioning, such as an elevated sensitivity to bodily sensations, may predispose some people to somatoform disorders (Kirmayer & Looper, 2007), but genetic factors do *not* appear to make much of a contribution to the development of these disorders (Hollifield, 2005). The available evidence suggests that these disorders are largely a function of personality and learning.

Personality Factors

People with certain types of personality traits seem to develop somatoform disorders more readily than others. The prime candidates appear to be people with *histrionic* personality characteristics (Nemiah, 1985; Slavney, 1990). The histrionic personality tends to be self-centered, suggestible, excitable, highly emotional, and overly dramatic. The personality trait of *neuroticism* also seems to elevate individuals' susceptibility to somatoform disorders (Noyes et al., 2005). In addition, research suggests that the pathological care-seeking behavior seen in these disorders may be caused by *insecure attachment styles* (see Chapter 11) that are rooted in early experiences with caregivers (Noyes et al., 2003).

Cognitive Factors

In recent years, theorists have devoted increased attention to how cognitive peculiarities might contribute to somatoform disorders. For example, Barsky (2001) asserts that some people focus excessive attention on their internal physiological processes and amplify normal bodily sensations into symptoms of distress, which lead them to pursue unnecessary medical treatment. Recent evidence suggests that people with somatoform disorders tend to draw catastrophic conclusions about minor bodily complaints (Salkovskis & Warwick, 2001). They also seem to apply a faulty standard of good health, equating health with a complete absence of symptoms and discomfort, which is unrealistic (Barsky et al., 1993; Rief, Hiller, & Margraf, 1998).

The Sick Role

Another consideration is that some people grow fond of the role associated with being sick (Hotopf, 2004; Pilowsky, 1993). Their complaints of physical symptoms may be reinforced by indirect benefits derived from their illness (Schwartz, Slater, & Birchler, 1994). What benefits might be derived from physical illness? One payoff is that becoming ill is a superb way to avoid having to confront life's challenges. Many people with somatoform disorders are avoiding facing up to marital problems, career frustrations, family responsibilities, and the like. After all, when you're sick, others cannot place great demands on you. Another benefit is that physical problems can provide a convenient excuse when people fail, or worry about failing, in endeavors that are critical to their self-esteem (Organista & Miranda, 1991). Attention from others is another payoff that may reinforce complaints of physical illness. When people become ill, they command the attention of family, friends, co-workers, neighbors, and doctors.

concept check 14.2

Distinguishing Anxiety and Somatoform Disorders

Check your understanding of the nature of anxiety and somatoform disorders by making preliminary diagnoses for the cases described below. Read each case summary and write your tentative diagnosis in the space provided. The answers are in Appendix A.

1. Malcolm religiously follows an exact schedule every day. His showering and grooming ritual takes two hours. He follows the same path in walking to his classes every day, and he always sits in the same seat in each class. He can't study until his apartment is arranged perfectly. Although he tries not to, he thinks constantly about flunking out of school. Both his grades and his social life are suffering from his rigid routines.

   Preliminary diagnosis: _____

2. Jane has been unemployed for the last eight years because of poor health. She has suffered through a bizarre series of illnesses of mysterious origin. Troubles with devastating headaches were followed by months of chronic back pain. Then she developed respiratory problems, frequently gasping for breath. Her current problem is stomach pain. Physicians have been unable to find any physical basis for her maladies.

   Preliminary diagnosis: _____

3. Nathan owns a small restaurant that's in deep financial trouble. He dreads facing the possibility that his restaurant will fail. One day, he suddenly loses all feeling in his right arm and the ability to control the arm. He's hospitalized for his condition, but physicians can't find any organic cause for his arm trouble.

   Preliminary diagnosis: _____

REVIEW of Key Points

14.8 Somatoform disorders are physical ailments that cannot be fully explained by organic conditions. Somatization disorder is characterized by a history of diverse physical complaints, whereas conversion disorder involves a loss of physical function in a single organ system. Hypochondriasis is marked by incessant worry about health concerns.

14.9 These disorders often emerge in people with highly suggestible, histrionic personalities, those high in neuroticism, and those who focus excess attention on their internal physiological processes. Somatoform disorders may be a learned avoidance strategy wherein the sick role is reinforced by attention and sympathy.

Dissociative Disorders

Dissociative disorders are probably the most controversial set of disorders in the diagnostic system, sparking heated debate among normally subdued researchers and clinicians (Loewenstein & Putnam 2005). *Dissociative disorders* **are a class of disorders in which people lose contact with portions of their consciousness or memory, resulting in disruptions in their sense of identity.** We'll describe three dissociative syndromes—dissociative amnesia, dissociative fugue, and dissociative identity disorder—all of which appear to be relatively uncommon, although good data on the prevalence of these disorders are scarce (Kihlstrom, 2005b).

Dissociative Amnesia and Fugue

Dissociative amnesia and fugue are overlapping disorders characterized by serious memory deficits. *Dissociative amnesia* **is a sudden loss of memory for important personal information that is too extensive to be due to normal forgetting.** Memory losses may occur for a single traumatic event (such as an automobile accident or home fire) or for an extended period of time surrounding the event. Cases of amnesia have been observed after people have experienced disasters, accidents, combat stress, physical abuse, and rape, or after they have witnessed the violent death of a parent, among other things (Arrigo & Pezdek, 1997; Cardena & Gleaves, 2007). In *dissociative fugue,* **people lose their memory for their entire lives along with their sense of personal identity.** These people forget their name, their family, where they live, and where they work! Despite this wholesale forgetting, they remember matters unrelated to their identity, such as how to drive a car and how to do math.

Dissociative Identity Disorder

Dissociative identity disorder (DID) **involves the coexistence in one person of two or more largely complete, and usually very different, personalities.** The name for this disorder used to be *multiple personality disorder,* which still enjoys informal use. In dissociative identity disorder, the divergences in behavior go far beyond those that people normally display in adapting to different roles in life. People with "multiple personalities" feel that they have more than one identity. Each personality has his or her own name, memories, traits, and physical mannerisms. Although rare, this "Dr. Jekyll and Mr.

Hyde" syndrome is frequently portrayed in novels, television shows, and movies, such as the *Three Faces of Eve,* a classic 1957 film starring Joanne Woodward, and the satirical film *Me, Myself, and Irene,* a 2000 release starring Jim Carrey. In popular media portrayals, the syndrome is often mistakenly called *schizophrenia.* As you will see later, schizophrenic disorders are entirely different.

In dissociative identity disorder, the various personalities generally report that they are unaware of each other (Eich et al., 1997), although doubts have been raised about the accuracy of this assertion (Allen & Iacono, 2001). The alternate personalities commonly display traits that are quite foreign to the original personality. For instance, a shy, inhibited person might develop a flamboyant, extraverted alternate personality. Transitions between identities often occur suddenly. The disparities between identities can be bizarre, as different personalities may assert that they are different in age, race, gender, and sexual orientation (Kluft, 1996). Dissociative identity disorder rarely occurs in isolation. Most DID patients also have a history of anxiety, mood, or personality disorders (Ross, 1999).

Starting in the 1970s, a dramatic increase was seen in the diagnosis of multiple-personality disorder (Kihlstrom, 2001, 2005b). Only 79 well-documented cases had accumulated up through 1970, but by the late-1990s about 40,000 cases were estimated to have been reported (Lilienfeld & Lynn, 2003). Some theorists believe that these disorders used to be underdiagnosed—that is, they often went undetected (Maldonado & Spiegel, 2003a). However, other theorists argue that a handful of clinicians have begun overdiagnosing the condition and that some clinicians even *encourage and contribute* to the emergence of DID (McHugh, 1995; Powell & Gee, 1999). Consistent with this view, a survey of all the psychiatrists in Switzerland found that 90% of them had never seen a case of dissociative identity disorder, whereas three of the psychiatrists had each seen more than 20 DID patients (Modestin, 1992). The data from this study suggest that 6 psychiatrists (out of 655 surveyed) accounted for two-thirds of the dissociative identity disorder diagnoses in Switzerland.

Etiology of Dissociative Disorders

Psychogenic amnesia and fugue are usually attributed to excessive stress. However, relatively little is known

about why this extreme reaction to stress occurs in a tiny minority of people but not in the vast majority who are subjected to similar stress. Some theorists speculate that certain personality traits—fantasy proneness and a tendency to become intensely absorbed in personal experiences—may make some people more susceptible to dissociative disorders, but adequate evidence is lacking on this line of thought (Kihlstrom, Glisky, & Angiulo, 1994).

The causes of dissociative identity disorders are particularly obscure. Some skeptical theorists, such as Nicholas Spanos (1994, 1996) and others (Gee, Allen, & Powell, 2003; Lilienfeld et al., 1999), believe that people with multiple personalities are engaging in intentional role playing to use mental illness as a face-saving excuse for their personal failings. Spanos also argues that a small minority of therapists help create multiple personalities in their patients by subtly encouraging the emergence of alternate personalities. According to Spanos, dissociative identity disorder is a creation of modern North American culture, much as demonic possession was a creation of early Christianity. To bolster his argument, he discusses how multiple-personality patients' symptom presentations seem to have been influenced by popular media. For example, the typical patient with dissociative identity disorder used to report having two or three personalities, but since the publication of *Sybil* (Schreiber, 1973) and other books describing patients with many personalities, the average number of alternate personalities has climbed to about 15.

Despite these concerns, some clinicians are convinced that DID is an authentic disorder (Cardena & Gleaves, 2007). They argue that there is no incentive for either patients or therapists to manufacture cases of multiple personalities, which are often greeted with skepticism and outright hostility. They maintain that most cases of dissociative identity disorder are rooted in severe emotional trauma that occurred during childhood (Draijer & Langeland, 1999). A substantial majority of people with dissociative identity disorder report a childhood history of rejection from parents and physical and sexual abuse (Scroppo et al., 1998; Foote et al., 2006). In the final analysis, little is known about the causes of dissociative identity disorder, which remains a controversial diagnosis (Barry-Walsh, 2005). In one survey of American psychiatrists, only one-quarter of the respondents indicated that they felt there was solid evidence for the scientific validity of the DID diagnosis (Pope et al., 1999). Consistent with this finding, a more recent study found that scientific interest in DID has dwindled since the mid-1990s (Pope et al., 2006).

> **REVIEW of Key Points**
>
> **14.10** Dissociative amnesia involves sudden memory loss that is too extensive to be due to normal forgetting. In dissociative fugue people also lose their sense of identity. Dissociative identity disorder is marked by the coexistence of two or more very different personalities. Since the 1970s there has been a dramatic and controversial increase in the diagnosis of dissociative identity disorder.
>
> **14.11** Some theorists believe that people with dissociative identity disorder are engaging in intentional role playing to use an exotic mental illness as a face-saving excuse for their personal failings. Other theorists view DID as an authentic disorder rooted in emotional trauma that occurred during childhood.

Mood Disorders SIM9

What did Abraham Lincoln, Leo Tolstoy, Marilyn Monroe, Vincent Van Gogh, Ernest Hemingway, Winston Churchill, Virginia Wolff, Janis Joplin, Irving Berlin, Kurt Cobain, Francis Ford Coppola, Carrie Fisher, Ted Turner, Sting, Mike Wallace, Larry Flynt, Jane Pauley, and Ben Stiller have in common? Yes, they all achieved great prominence, albeit in different ways at different times. But, more pertinent to our interest, they all suffered from severe mood disorders. Although mood disorders can be terribly debilitating, people with mood disorders may still achieve greatness, because such disorders tend to be *episodic*. In other words, mood disturbances often come and go, interspersed among periods of normality.

Emotional fluctuations are natural, but some people are subject to extreme and sustained distortions of mood. ***Mood disorders* are a class of disorders marked by emotional disturbances of varied kinds that may spill over to disrupt physical, perceptual, social, and thought processes.** There are two basic types of mood disorders: unipolar and bipolar (see **Figure 14.11**). People with *unipolar disorder* experience emotional extremes at just one end of the mood continuum, as they are troubled only by *depression*. People with *bipolar disorder* are vulnerable to emotional extremes at both ends of the mood continuum, going through periods of both *depression* and *mania* (excitement and elation).

Major Depressive Disorder 11b

The line between normal dejection and unhappiness and abnormal depression can be difficult to draw (Kendler & Gardner, 1998). Ultimately, it requires a subjective judgment. Crucial considerations in this judgment include the duration of the depression and its disruptive effects. When a depression significantly impairs everyday adaptive behavior for more than a few weeks, there is reason for concern.

In *major depressive disorder* people show persistent feelings of sadness and despair and a loss of interest in previous sources of pleasure. Negative emotions form the heart of the depressive syndrome, but many other symptoms may also appear. The most common symptoms of major depression are summarized and compared with the symptoms of mania in Table 14.1. Depressed people often give up activities that they used to find enjoyable. For example, a depressed person might quit going bowling or might give up a favorite hobby such as photography. Alterations in appetite and sleep patterns are common. People with depression often lack energy. They tend to move sluggishly and talk slowly. Anxiety, irritability, and brooding are commonly observed. Self-esteem tends to sink as the depressed person begins to feel worthless. Depression plunges people into feelings of hopelessness, dejection, and boundless guilt. To make matters worse, people who suffer from depression often exhibit other disorders as well. Coexisting anxiety disorders and substance use disorders are particularly frequent (Boland & Keller, 2002).

The onset of depression can occur at any point in the life span, but a substantial majority of cases emerge before age 40 (Hammen, 2003). Depression occurs in children as well as adolescents and adults (Gruenberg & Goldstein, 2003). The vast majority (75%–95%) of people who suffer from depression experience more than one episode over the course of their lifetime (Dubovsky, Davies, & Dubovsky, 2003). In one longitudinal study, after recovery from a first episode of depression, the cumulative probability of recurrence was 25% after 1 year, 42% after two years, and 60% after 5 years (Solomon et al., 2000). The average number of depressive episodes is 5 to 6, and the average length of these episodes is about six months (Akiskal, 2005). The severity of depressive disorders varies considerably. When people display relatively mild symptoms of depression, they're

Table 14.1 Comparisons of Common Symptoms in Manic and Depressive Episodes

Characteristics	Manic Episode	Depressive Episode
Emotional	Elated, euphoric, very sociable, impatient at any hindrance	Gloomy, hopeless, socially withdrawn, irritable
Cognitive	Characterized by racing thoughts, flight of ideas, desire for action, and impulsive behavior; talkative, self-confident; experiencing delusions of grandeur	Characterized by slowness of thought processes, obsessive worrying, inability to make decisions, negative self-image, self-blame and delusions of guilt and disease
Motor	Hyperactive, tireless, requiring less sleep than usual, showing increased sex drive and fluctuating appetite	Less active, tired, experiencing difficulty in sleeping, showing decreased sex drive and decreased appetite

Mood disorders are common and have affected many successful, well-known people, such as Sheryl Crow and Harrison Ford.

given a diagnosis of *dysthymic disorder,* which consists of chronic depression that is insufficient in severity to justify diagnosis of a major depressive episode.

How common are depressive disorders? Well, estimates of the prevalence of depression vary quite a bit from one study to another because of the previously mentioned difficulty in drawing a line between normal dejection and abnormal depression. That said, depression is clearly a common disorder. The pooled data from the large-scale studies cited in Figure 14.5 yielded a lifetime prevalence estimate of 13%–14%. A recent study of a nationally representative sample of over 9000 adults estimated that the lifetime prevalence of depressive disorder was 16.2% (Kessler et al., 2003a). That estimate suggests that over 30 million people in the United States have suffered or will suffer from depression!

Research indicates that the prevalence of depression is about twice as high in women as it is in men (Rihmer & Angst, 2005). The many possible explanations for this gender gap are the subject of considerable debate. The gap does *not* appear to be attributable to differences in genetic makeup (Kessler et al., 2003a). A small portion of the disparity may be the result of women's elevated vulnerability to depression at certain points in their reproductive life cycle (Kornstein & Sloan, 2006). Obviously, only women have to worry abut the phenomena of postpartum and postmenopausal depression. Susan Nolen-Hoeksema (2001) argues that women experience more depression than men because they are far more likely to be victims of sexual abuse and somewhat more likely to endure poverty, sexual harassment, role constraints, and excessive pressure to be thin and attractive. In other words, she attributes the higher prevalence

of depression among women to their experience of greater stress and adversity. Nolen-Hoeksema also believes that women have a greater tendency than men to *ruminate* about setbacks and problems. Evidence suggests that this tendency to dwell on one's difficulties elevates vulnerability to depression, as we will discuss momentarily.

Bipolar Disorder   11b

Bipolar disorder **(formerly known as** *manic-depressive disorder***) is characterized by the experience of one or more manic episodes as well as periods of depression.** One manic episode is sufficient to qualify for this diagnosis. The symptoms seen in manic periods generally are the opposite of those seen in depression (see Table 14.1 for a comparison). In a manic episode, a person's mood becomes elevated to the point of euphoria. Self-esteem skyrockets as the person bubbles over with optimism, energy, and extravagant plans. He or she becomes hyperactive and may go for days without sleep. The individual talks rapidly and shifts topics wildly, as his or her mind races at breakneck speed. Judgment is often impaired. Some people in manic periods gamble impulsively, spend money frantically, or become sexually reckless. Like depressive disorders, bipolar disorders vary considerably in severity. People are given a diagnosis of *cyclothymic disorder* **when they exhibit chronic but relatively mild symptoms of bipolar disturbance.**

You may be thinking that the euphoria in manic episodes sounds appealing. If so, you are not entirely wrong. In their milder forms, manic states can seem attractive. The increases in energy, self-esteem, and optimism can be deceptively seductive. Because of the increase in energy, many bipolar patients report temporary surges of productivity and creativity (Goodwin & Jamison, 1990).

Although manic episodes may have some positive aspects, these periods often have a paradoxical negative undercurrent of irritability and depression (Dilsaver et al., 1999). Moreover, mild manic episodes usually escalate to higher levels that become scary and disturbing. Impaired judgment leads many victims to do things that they greatly regret later, as you'll see in the following case history:

Robert, a dentist, awoke one morning with the idea that he was the most gifted dental surgeon in his tristate area. He decided that he should try to provide services to as many people as possible, so that more people could benefit from his talents. Thus, he decided to remodel his two-chair dental office, installing 20 booths so that he could simultaneously attend to 20 patients. That same day he

"Those? Oh, just a few souvenirs from my bipolar-disorder days."

drew up plans for this arrangement, telephoned a number of remodelers, and invited bids for the work. Later that day, impatient to get rolling on his remodeling, he rolled up his sleeves, got himself a sledgehammer, and began to knock down the walls in his office. Annoyed when that didn't go so well, he smashed his dental tools, washbasins, and X-ray equipment. Later, Robert's wife became concerned about his behavior and summoned two of her adult daughters for assistance. The daughters responded quickly, arriving at the family home with their husbands. In the ensuing discussion, Robert—after bragging about his sexual prowess—made advances toward his daughters. He had to be subdued by their husbands. (Adapted from Kleinmuntz, 1980, p. 309)

Although not rare, bipolar disorders are much less common than unipolar disorders. Bipolar disorder affects about 1%–2.5% of the population (Dubovsky et al., 2003). Unlike depressive disorder, bipolar disorder is seen equally often in males and females (Rihmer & Angst, 2005). As **Figure 14.12** shows, the onset of bipolar disorder is age-related, with the age of 25 being the median age of onset (Miklowitz & Johnson, 2007). The mood swings in bipolar disorder can be patterned in many ways. About 20% of bipolar patients exhibit a *rapid-cycling pattern,* which means they go through four or more manic or depressive episodes within a year.

Mood Disorders and Suicide

A tragic, heartbreaking problem associated with mood disorders is suicide, which is the eleventh leading cause of death in the United States, accounting for about 30,000 deaths annually. Official statistics may underestimate the scope of the problem, as many suicides are disguised as accidents, either by the suicidal person or by the survivors who try to cover up afterward. Moreoever, experts estimate

that suicide attempts may outnumber completed suicides by a ratio of as much as 20 to 1 (Sudak, 2005). Anyone can commit suicide, but some groups are at higher risk than others (Carroll-Ghosh, Victor, & Bourgeois, 2003). Evidence suggests that women *attempt* suicide three times more often than men. But men are more likely to actually kill themselves in an attempt, so they *complete* four times as many suicides as women. In regard to age, completed suicides peak in the over-75 age bracket.

With the luxury of hindsight, it is recognized that about 90% of the people who complete suicide suffer from some type of psychological disorder, although in some cases this disorder may not be readily apparent beforehand (Dawkins, Golden, & Fawcett, 2003). As you might expect, suicide rates are highest for people with mood disorders, who account for about 60% of completed suicides (Mann & Currier, 2006). Both bipolar disorder and depression are associated with dramatic elevations in suicide rates. Studies suggest that the lifetime risk of completed suicide is about 15%–20% in people with bipolar disorder and about 10% in those who have grappled with depression (Sudak, 2005). Smaller elevations in suicide rates are seen among people who suffer from schizophrenia, alcoholism, and substance abuse (Mann & Currier, 2006). Unfortunately, there is no foolproof way to prevent suicidal persons from taking their own life, but some useful tips are compiled in **Figure 14.13** (on the next page).

Etiology of Mood Disorders 11b

Quite a bit is known about the etiology of mood disorders, although the puzzle certainly hasn't been assembled completely. There appear to be a number of routes into these disorders, involving intricate interactions among psychological and biological factors.

Suicide Prevention Tips

1. *Take suicidal talk seriously.* When people talk about suicide in vague generalities, it's easy to dismiss it as idle talk and let it go. However, people who talk about suicide are a high-risk group, and their veiled threats should not be ignored. The first step in suicide prevention is to directly ask such people if they're contemplating suicide.

2. *Provide empathy and social support.* It is important to show the suicidal person that you care. People often contemplate suicide because they see the world around them as indifferent and uncaring. Thus, you must demonstrate to the suicidal person that you are genuinely concerned. Suicide threats are often a last-ditch cry for help. It is therefore imperative that you offer to help.

3. *Identify and clarify the crucial problem.* The suicidal person is often confused and feels lost in a sea of frustration and problems. It is a good idea to try to help sort through this confusion. Encourage the person to try to identify the crucial problem. Once it is isolated, the problem may not seem quite so overwhelming.

4. *Do not promise to keep someone's suicidal ideation secret.* If you really feel like someone's life is in danger, don't agree to keep his or her suicidal plans secret to preserve your friendship.

5. *In an acute crisis, do not leave a suicidal person alone.* Stay with the person until additional help is available. Try to remove any guns, drugs, sharp objects, and so forth that might provide an available means to commit suicide.

6. *Encourage professional consultation.* Most mental health professionals have some experience in dealing with suicidal crises. Many cities have suicide prevention centers with 24-hour hotlines. These centers are staffed with people who have been specially trained to deal with suicidal problems. It is important to try to get a suicidal person to seek professional assistance.

Genetic Vulnerability   11b

Twin studies suggest that genetic factors are involved in mood disorders (Berrettini, 2006; Kelsoe, 2005). Concordance rates average around 65% for identical twins but only 14% for fraternal twins, who share less genetic similarity (see **Figure 14.14**). Thus, evidence suggests that heredity can create a *predisposition* to mood disorders. Environmental factors probably determine whether this predisposition is converted into an actual disorder. The influence of genetic factors appears to be stronger for bipolar disorders than for unipolar disorders (Kieseppa et al., 2004). Some promising results have been reported in *genetic mapping* studies that have attempted to pinpoint the specific genes that shape vulnerabil-

ity to mood disorders (Caspi et al., 2003; Holmans et al., 2007). However, results have been disturbingly inconsistent, and scientists do *not* appear to be on the verge of unraveling the genetic code for mood disorders, which probably depend on subtle variations in constellations of many genes (Kendler, 2005a, 2005b; Merikangas & Risch, 2003).

Neurochemical and Neuroanatomical Factors   11b

Heredity may influence susceptibility to mood disorders by creating a predisposition toward certain types of neurochemical abnormalities in the brain. Correlations have been found between mood disorders and abnormal levels of two neurotransmitters in the brain: norepinephrine and serotonin (Sher & Mann, 2003), although other neurotransmitter disturbances may also contribute (Thase, Jindal, & Howland, 2002). The details remain elusive, but low levels of serotonin appear to be a crucial factor underlying most forms of depression (Flores et al., 2004). A variety of drug therapies are fairly effective in the treatment of severe mood disorders. Most of these drugs are known to affect the availability (in the brain) of the neurotransmitters that have been related to mood disorders (Dubovsky et al., 2003). Since this effect is unlikely to be a coincidence, it bolsters the plausibility of the idea that neurochemical changes produce mood disturbances. That said, after 40 years of enormous research effort, the neurochemical bases of mood disorders remain more mysterious than scientists would like (Delgado & Moreno, 2006).

Studies have also found some interesting correlations between mood disorders and a variety of structural abnormalities in the brain (Flores et al., 2004). Perhaps the best documented correlation is the association between depression and *reduced hippocampal volume* (Campbell et al., 2004; Videbech, 2006). The *hippocampus,* which is known to play a major role in memory consolidation (see Chapter 7), tends to be about 8%–10% smaller in depressed subjects than in normal subjects (Videbech & Ravnkilde, 2004). A fascinating new theory of the biological bases of depression may be able to account for this finding. The springboard for this theory is the recent discovery that the human brain continues to generate new neurons in adulthood, especially in the hippocampal formation (Gage, 2002). As noted elsewhere (see Chapters 3, 7, and 13), this process is called *neurogenesis*. Recent evidence suggests that depression occurs when major life stress causes neurochemical reactions that suppress neurogenesis, resulting in reduced hippocampal volume (Jacobs, 2004; Warner-Schmidt & Duman, 2006). According to this view,

Figure 14.14

Twin studies of mood disorders. The concordance rate for mood disorders in identical twins is much higher than that for fraternal twins, who share less genetic overlap. These results suggest that there must be a genetic predisposition to mood disorders. (Data from Berrettini, 2006)

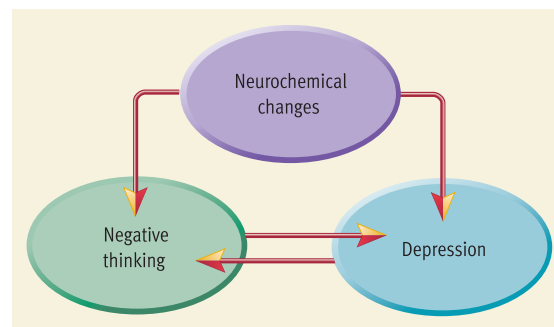
Relationship	Genetic relatedness	Concordance rate (%) (lifetime risk)
Identical twins	100%	(bar extending to ~65)
Fraternal twins	50%	(bar extending to ~14)

it is the suppression of neurogenesis that is the central cause of depression and antidepressant drugs are successful because they promote neurogenesis (Duman & Monteggia, 2006). A great deal of additional research will be required to fully test this innovative new model of the biological bases of depressive disorders.

Cognitive Factors

A variety of theories emphasize how cognitive factors contribute to depressive disorders (Christensen, Carney, & Segal, 2006). We will discuss Aaron Beck's (1976, 1987) influential cognitive theory of depression in Chapter 15, where his approach to therapy is described. In this section, we'll examine Martin Seligman's *learned helplessness model* of depression. Based largely on animal research, Seligman (1974) proposed that depression is caused by *learned helplessness*—passive "giving up" behavior produced by exposure to unavoidable aversive events (such as uncontrollable shock in the laboratory). He originally considered learned helplessness to be a product of conditioning but eventually revised his theory, giving it a cognitive slant. The reformulated theory of learned helplessness asserts that the roots of depression lie in how people explain the setbacks and other negative events that they experience (Abramson, Seligman, & Teasdale, 1978). According to Seligman (1990), people who exhibit a *pessimistic explanatory style* are especially vulnerable to depression. These people tend to attribute their setbacks to their personal flaws instead of situational factors, and they tend to draw global, far-reaching conclusions about their personal inadequacies based on these setbacks.

In accord with this line of thinking, Susan Nolen-Hoeksema (1991, 2000) has found that depressed people who *ruminate* about their depression remain depressed longer than those who try to distract themselves. People who respond to depression with rumination repetitively focus their attention on their depressing feelings, thinking constantly about how sad, lethargic, and unmotivated they are. According to Nolen-Hoeksema (1995), excessive rumination tends to extend and amplify individuals' episodes of depression. As we noted earlier, she believes that women are more likely to ruminate than men and that this disparity may be one of the primary reasons why depression is more prevalent in women.

In sum, cognitive models of depression maintain that negative thinking is what leads to depression in many people. The principal problem with cognitive theories is their difficulty in separating cause from effect (Feliciano & Arean, 2007). Does negative thinking cause depression? Or does depression cause negative thinking (see **Figure 14.15**)? A *clear* demonstration of a causal link between negative thinking and depression is not possible because it would require manipulating people's cognitive style (which is not easy to change) in sufficient degree to produce full-fledged depressive disorders (which would not be ethical). However, the research reported in our Featured Study provided impressive evidence consistent with a causal link between negative thinking and vulnerability to depression.


Susan Nolen-Hoeksema

"By adolescence, girls appear to be more likely than boys to respond to stress and distress with rumination—focusing inward on feelings of distress and personal concerns rather than taking action to relieve their distress."

Figure 14.15

Interpreting the correlation between negative thinking and depression. Cognitive theories of depression assume that consistent patterns of negative thinking cause depression. Although these theories are highly plausible, depression could cause negative thoughts, or both could be caused by a third factor, such as neurochemical changes in the brain.

Does Negative Thinking Cause Depression?

This article describes a series of studies conducted at Temple University and at the University of Wisconsin, collectively referred to as the Temple-Wisconsin Cognitive Vulnerability to Depression Project. Although the article reports on many facets of the project, we will focus on the study intended to test the hypothesis that a negative cognitive style is predictive of elevated vulnerability to depression.

Method

Participants. Over 5,000 first-year students at the two universities responded to two measures of negative thinking. Students who scored in the highest quartile on both measures were characterized as having a *high risk* for depression, while those who scored in the lowest quartile on both measures were characterized as having a *low risk* for depression. Randomly selected subsets of these two groups were invited for additional screening to eliminate anyone who was *currently* depressed or suffering from any other major psychological disorder. People who had *previously* suffered from depression or other disorders were not eliminated. The final sample consisted of 173 students in the high-risk group and 176 students in the low-risk group.

Follow-up assessments. Self-report measures and structured interviews were used to evaluate the mental health

FEATURED

STUDY

of the participants every 6 weeks for the first two years and then every 16 weeks for an additional three years. The assessments were conducted by interviewers who were blind regarding the subjects' risk group status. The present report summarized the follow-up data for the first two and one-half years of the study. The results were given separately for those who did and did not have a prior history of depression.

Results

The data for students who had no prior history of depression showed dramatic differences between the high-risk and low-risk groups in vulnerability to depression. During the relatively brief 2.5-year period, a major depressive disorder emerged in 17% of the high-risk students in comparison to only 1% of the low-risk students. The high-risk subjects also displayed a much greater incidence of minor depressive episodes, as you can see in the left panel of **Figure 14.16**. The right panel of **Figure 14.16** shows the comparisons for participants who had a prior history of depression (but were not depressed or suffering from any other disorder at the beginning of the study). The data show that high-risk subjects were more vulnerable to a recurrence of both major and minor depression during the 2.5-year follow-up.

Discussion

The high-risk participants, who exhibited a negative cognitive style, were consistently found to have an elevated likelihood of developing depressive disorders. Hence, the authors conclude that their results provide strong support for the cognitive vulnerability hypothesis, which asserts that negative thinking makes people more vulnerable to depression.

Comment

Previous studies of the correlation between negative thinking and depression used *retrospective designs,* which look backward in time from known outcomes. For example, investigators might compare depressed subjects versus nondepressed subjects on some measure of negative thinking. What makes the design retrospective is that the researchers already know which people experienced the outcome of depression. Retrospective designs can yield useful information, but they don't provide much insight about causation. Why? Because if you find an association between depression and negative thinking you can't determine whether the negative thinking preceded the depression or the depression preceded the negative thinking. The present study used a *prospective design* which moves forward in time, testing hypotheses about future outcomes. Prospective studies are much more difficult and time-consuming to conduct, but they can provide more insight about causation because they can show that one event (in this instance, the development of a negative cognitive style) preceded another (the occurrence of depression). The data are still correlational, so they cannot definitively establish a causal link, but they provide much stronger evidence in favor of causation than retrospective data. Thus, the research by Alloy and her colleagues provides the best evidence to date in support of the hypothesis that negative thinking contributes to the causation of depressive disorders.
Figure 14.16

Negative thinking and prediction of depression. Alloy and colleagues (1999) measured the cognitive styles of first-year college students and characterized the students as high risk or low risk for depression. These graphs show the percentage of these students who experienced major or minor episodes of depression over the next 2.5 years. As you can see, the high-risk students who exhibited a negative thinking style proved to be much more vulnerable to depression.

Interpersonal Roots

Behavioral approaches to understanding depression emphasize how inadequate social skills put people on the road to depressive disorders (see **Figure 14.17**; Coyne, 1999). According to this notion, depression-prone people lack the social finesse needed to acquire many important kinds of reinforcers, such as good friends, top jobs, and desirable spouses. This paucity of reinforcers could understandably lead to negative emotions and depression. Consistent with this theory, researchers have found correlations between poor social skills and depression (Petty, Sachs-Ericsson, & Joiner, 2004).

Another interpersonal factor is that depressed people tend to be depressing (Joiner & Katz, 1999). Individuals suffering from depression often are irritable and pessimistic. They complain a lot and aren't particularly enjoyable companions. They also alienate people by constantly asking for reassurances about their relationships and their worth (Burns et al., 2006). As a consequence, depressed people tend to court rejection from those around them (Joiner & Metalsky, 1995). Depressed people thus have fewer sources of social support than nondepressed people, which may aggravate and deepen their depression (Potthoff, Holahan, & Joiner, 1995). Moreover, recent evidence suggests that lack of social support may make a larger contribution to depression in women than in men (Kendler, Myers, & Prescott, 2005). To compound these problems, evidence indicates that depressed people may gravitate to partners who view them unfavorably and hence reinforce their negative views of themselves (Joiner, 2002).

Precipitating Stress

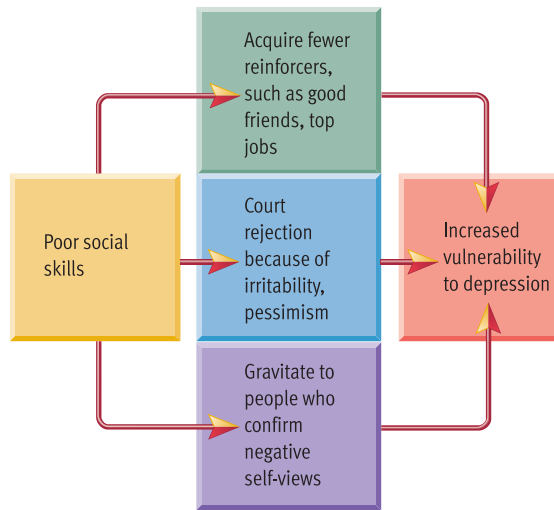
Mood disorders sometimes appear mysteriously in people who are leading benign, nonstressful lives. For this reason, experts used to believe that mood


Figure 14.17

Interpersonal factors in depression. Behavioral theories about the etiology of depression emphasize how inadequate social skills may contribute to the development of the disorder through several mechanisms, as diagrammed here.

disorders are not influenced much by stress. However, advances in the measurement of personal stress have altered this picture. The evidence available today suggests a moderately strong link between stress and the onset of mood disorders (Hammen, 2005; Kendler, Kuhn, & Prescott, 2004). Stress also appears to affect how people with mood disorders respond to treatment and whether they experience a relapse of their disorder (Monroe & Hadjiyannakis, 2002).

Of course, many people endure great stress without getting depressed. The impact of stress varies, in part, because people vary in their degree of *vulnerability* to mood disorders (Lewinsohn, Joiner, & Rohde, 2001). Similar interactions between stress and vulnerability probably influence the development of many kinds of disorders, including those that are next on our agenda—the schizophrenic disorders.

REVIEW of Key Points

14.12 Major depression is marked by profound sadness, slowed thought processes, and loss of interest in previous sources of pleasure. Bipolar disorder involves the experience of both manic episodes and periods of depression. Manic episodes are characterized by inflated self-esteem, high energy, grandiose plans, and racing thoughts. Depression is extremely common, whereas the lifetime prevalence of bipolar disorder is about 1%–2.5%. Both types of mood disorders are associated with greatly elevated rates of suicide.

14.13 Evidence indicates that people vary in their genetic vulnerability to mood disorders. These disorders are accompanied by changes in neurochemical activity in the brain. Abnormalities at norepinephrine and serotonin synapses appear par-

ticularly critical. Reduced hippocampal volume and suppressed neurogenesis are also associated with depression.

14.14 Cognitive models posit that negative thinking contributes to depression. A pessimistic explanatory style has been implicated, as has a tendency to ruminate about one's problems. The Featured Study reported impressive evidence in support of the idea that negative thinking can contribute to the causation of depression.

14.15 Interpersonal inadequacies may contribute to depressive disorders. Poor social skills may lead to a paucity of life's reinforcers and frequent rejection. Mood disorders may also be precipitated by high stress, especially in those who are particularly vulnerable to mood disorders.

Schizophrenic Disorders   SIM9

Literally, *schizophrenia* means "split mind." However, when Eugen Bleuler coined the term in 1911 he was referring to the fragmentation of thought processes seen in the disorder—not to a "split personality." Unfortunately, writers in the popular media often assume that the split-mind notion, and thus schizophrenia, refers to the rare syndrome in which a person manifests two or more personalities. As you have already learned, this syndrome is actually called *dissociative identity disorder* or *multiple-personality disorder*. Schizophrenia is a much more common, and altogether different, type of disorder.

Schizophrenic disorders **are a class of disorders marked by delusions, hallucinations, disorganized speech, and deterioration of adaptive behavior.** People with schizophrenic disorders often display some of the same symptoms seen in people with severe mood disorders; however, disturbed *thought* lies at the core of schizophrenic disorders, whereas disturbed *emotion* lies at the core of mood disorders.

How common is schizophrenia? Prevalence estimates suggest that about 1% of the population may suffer from schizophrenic disorders (Lauriello, Bustillo, & Keith, 2005). That may not sound like much, but it means that in the United States alone there may be several million people troubled by schizophrenic disturbances. Moreover, schizophrenia is an extremely costly illness for society, because it is a severe, debilitating disorder that tends to have an early onset and often requires lengthy hospital care (Buchanan & Carpenter, 2000). Because of these considerations, the financial impact of schizophrenia is estimated to exceed the costs of all types of cancers combined (Buchanan & Carpenter, 2005).

General Symptoms   11c

There are a number of distinct schizophrenic syndromes, but they share some general characteristics that we will examine before looking at the subtypes. Many of these characteristics are apparent in the following case history (adapted from Sheehan, 1982).

Sylvia was first given a diagnosis of schizophrenia at age 15. She has been in and out of many types of psychiatric facilities since then. She has never been able to hold a job for any length of time. During severe flare-ups of her disorder, her personal hygiene deteriorates. She rarely washes, she wears clothes that neither fit nor match, she smears makeup on heavily but randomly, and she slops food all over herself.

Sylvia occasionally hears voices talking to her. She tends to be argumentative, aggressive, and emotionally volatile. Over the years, she has been involved in innumerable fights with fellow patients, psychiatric staff members, and strangers. Her thoughts can be highly irrational, as is apparent from the following quote, which was recorded while she was a patient in a psychiatric facility called Creedmoor:

"Mick Jagger wants to marry me. If I have Mick Jagger, I don't have to covet Geraldo Rivera. Mick Jagger is St. Nicholas and the Maharishi is Santa Claus. I want to form a gospel rock group called the Thorn Oil, but Geraldo wants me to be the music critic on Eyewitness News, so what can I do? Got to listen to my boyfriend. Teddy Kennedy cured me of my ugliness. I'm pregnant with the son of God. I'm going to marry David Berkowitz and get it over with. Creedmoor is the headquarters of the American Nazi Party. They're eating the patients here. Archie Bunker wants me to play his niece on his TV show. I work for Epic Records. I'm Joan of Arc. I'm Florence Nightingale. The door between the ward and the porch is the dividing line between New York and California. Divorce isn't a piece of paper, it's a feeling. Forget about Zip Codes. I need shock treatments. The body is run by electricity. My wiring is all faulty." (Sheehan, 1982, pp. 104–105)

Sylvia's case clearly shows that schizophrenic thinking can be bizarre and that schizophrenia can be a severe and debilitating disorder. Although no single symptom is inevitably present, the following symptoms are commonly seen in schizophrenia (Ho, Black, & Andreasen, 2003; Lindenmayer & Khan, 2006).

Delusions and Irrational Thought

Cognitive deficits and disturbed thought processes are the central, defining feature of schizophrenic disorders (Barch, 2003; Heinrichs, 2005). Various kinds of delusions are common. *Delusions* **are false beliefs that are maintained even though they clearly are out of touch with reality.** For example, one patient's delusion that he was a tiger (with a deformed body) persisted for more than 15 years (Kulick, Pope, & Keck, 1990). More typically, affected persons believe that their private thoughts are being broadcast to other people, that thoughts are being injected into their mind against their will, or that their thoughts are being controlled by some external force (Maher, 2001). In *delusions of grandeur*, people maintain that they are famous or important.

Sylvia expressed an endless array of grandiose delusions, such as thinking that Mick Jagger wanted to marry her, that she had dictated the hobbit stories to J. R. R. Tolkien, and that she was going to win the Nobel prize for medicine.

Another characteristic of schizophrenia is that the person's train of thought deteriorates. Thinking becomes chaotic rather than logical and linear. The person experiences a "loosening of associations," as he or she shifts topics in disjointed ways. The quotation from Sylvia illustrates this symptom dramatically. The entire quote involves a wild flight of ideas, but at one point (beginning with the sentence "Creedmoor is the headquarters . . .") she rattles off ten consecutive sentences that have no apparent connection to each other.

Deterioration of Adaptive Behavior

Schizophrenia usually involves a noticeable deterioration in the quality of the person's routine functioning in work, social relations, and personal care. Friends will often make remarks such as "Hal just isn't himself anymore." This deterioration is readily apparent in Sylvia's inability to get along with others or to function in the work world. It's also apparent in her neglect of personal hygiene.

Hallucinations

A variety of perceptual distortions may occur with schizophrenia, the most common being auditory hallucinations, which are reported by about 75% of patients (Combs & Mueser, 2007). *Hallucinations are sensory perceptions that occur in the absence of a real, external stimulus or are gross distortions of perceptual input.* People with schizophrenia frequently report that they hear voices of nonexistent or absent people talking to them. Sylvia, for instance, said she heard messages from Paul McCartney. These voices often provide an insulting, running commentary on the person's behavior ("You're an idiot for shaking his hand"). They may be argumentative ("You don't need a bath"), and they may issue commands ("Prepare your home for visitors from outer space").

Disturbed Emotion

Normal emotional tone can be disrupted in schizophrenia in a variety of ways. Although it may not be an accurate indicator of their underlying emotional experience (Kring, 1999), some victims show little emotional responsiveness, a symptom referred to as "blunted or flat affect." Others show inappropriate emotional responses that don't jibe with the situation or with what they are saying. For instance, a schizophrenic patient might cry over a silly cartoon

and then laugh about a news story describing a child's tragic death. People with schizophrenia may also become emotionally volatile. This pattern was displayed by Sylvia, who often overreacted emotionally in erratic, unpredictable ways.

Subtypes, Course, and Outcome

11c

Four subtypes of schizophrenic disorders are recognized, including a category for people who don't fit neatly into any of the first three categories. The major symptoms of each subtype are as follows (Ho et al., 2003; Kirkpatrick & Tek, 2005).

Paranoid Type

As its name implies, *paranoid schizophrenia is dominated by delusions of persecution, along with delusions of grandeur.* In this common form of schizophrenia, people come to believe that they have many enemies who want to harass and oppress them. They may become suspicious of friends and relatives, or they may attribute the persecution to mysterious, unknown persons. They are convinced that they are being watched and manipulated in malicious ways. To make sense of this persecution, they often develop delusions of grandeur. They believe that they must be enormously important people, frequently seeing themselves as great inventors or as famous religious or political leaders. For example, in the case described at the beginning of the chapter, Ed's belief that he was president of the United States was a delusion of grandeur.

Catatonic Type

Catatonic schizophrenia is marked by striking motor disturbances, ranging from muscular rigidity to random motor activity. Some patients go into an extreme form of withdrawal known as a catatonic stupor. They may remain virtually motionless and seem oblivious to the environment around them for long periods of time. Others go into a state of catatonic excitement. They become hyperactive and incoherent. Some alternate between these dramatic extremes. The catatonic subtype is not particularly common, and its prevalence seems to be declining.

Disorganized Type

In *disorganized schizophrenia,* a particularly severe deterioration of adaptive behavior is seen. Prominent symptoms include emotional indifference, frequent incoherence, and virtually complete social withdrawal. Aimless babbling and giggling are common. Delusions often center on bodily functions ("My brain is melting out my ears").

Undifferentiated Type

People who are clearly schizophrenic but who cannot be placed into any of the three previous categories are said to have *undifferentiated schizophrenia,* which is marked by idiosyncratic mixtures of schizophrenic symptoms. The undifferentiated subtype is fairly common.

Positive Versus Negative Symptoms

Many theorists have raised doubts about the value of dividing schizophrenic disorders into the four subtypes just described (Sanislow & Carson, 2001). Critics note that the catatonic subtype is disappearing and that undifferentiated cases aren't so much a subtype as a hodgepodge of "leftovers." Critics also point out that there aren't meaningful differences between the subtypes in etiology, prognosis, or response to treatment. The absence of such differences casts doubt on the value of the current classification scheme.

Because of such problems, Nancy Andreasen (1990) and others (Carpenter, 1992; McGlashan & Fenton, 1992) have proposed an alternative approach to subtyping. This new scheme divides schizophrenic disorders into just two categories based on the predominance of negative versus posi-

Courtesy of Nancy Andreasen, M.D.

Nancy Andreasen

"Schizophrenia disfigures the emotional and cognitive faculties of its victims, and sometimes nearly destroys them."

tive symptoms. *Negative symptoms* involve behavioral deficits, such as flattened emotions, social withdrawal, apathy, impaired attention, and poverty of speech. *Positive symptoms* involve behavioral excesses or peculiarities, such as hallucinations, delusions, bizarre behavior, and wild flights of ideas.

Theorists advocating this scheme hoped to find consistent differences between the two subtypes in etiology, prognosis, and response to treatment, and some progress along these lines *has* been made. For example, a predominance of positive symptoms is associated with better adjustment prior to the onset of schizophrenia and greater responsiveness to treatment (Combs & Mueser, 2007; Galderisi et al., 2002). However, the assumption that patients can be placed into discrete categories based on this scheme now seems untenable. Most patients exhibit both types of symptoms and vary only in the *degree* to which positive or negative symptoms dominate (Black & Andreasen, 1999). Although it seems fair to say that the distinction between positive and negative symptoms is enhancing our understanding of schizophrenia, it has not yielded a classification scheme that can replace the traditional subtypes of schizophrenia.

Course and Outcome

Schizophrenic disorders usually emerge during adolescence or early adulthood, with 75% of cases manifesting by the age of 30 (Perkins, Miller-Anderson, & Lieberman, 2006). Those who develop schizophrenia usually have a long history of peculiar behavior and cognitive and social deficits, although most do not manifest a full-fledged psychological disorder during childhood (Walker et al., 2004). The emergence of schizophrenia may be sudden, but it is usually insidious and gradual. Once the disorder clearly emerges, its course is variable, but patients tend to fall into three broad groups. Some patients, presumably those with milder disorders, are treated successfully and enjoy a full recovery. Other patients experience a partial recovery and they can return to independent living for a time. However, they experience regular relapses over the remainder of their lives. Finally, a third group of patients endure chronic illness marked by relentless deterioration and extensive hospitalization. Estimates of the percentage of patients falling in each category vary. Overall, the preponderance of studies have suggested that only about 20 percent of schizophrenic patients enjoy a full recovery (Perkins et al., 2006; Robinson et al., 2004). However, to some extent, this low recovery rate may reflect the poor to mediocre quality of mental health care available for severe disorders in many countries (see Chapter 15). When

concept check 14.3

Distinguishing Schizophrenic and Mood Disorders

Check your understanding of the nature of schizophrenic and mood disorders by making preliminary diagnoses for the cases described below. Read each case summary and write your tentative diagnosis in the space provided. The answers are in Appendix A.

1. Max hasn't slept in four days. He's determined to write the "great American novel" before his class reunion, which is a few months away. He expounds eloquently on his novel to anyone who will listen, talking at such a rapid pace that no one can get a word in edgewise. He feels like he's wired with energy and is supremely confident about the novel, even though he's only written 10 to 20 pages. Last week, he charged $5000 worth of new computer equipment and software, which is supposed to help him write his book.

   Preliminary diagnosis: _____

2. Eduardo maintains that he invented the atomic bomb, even though he was born after its invention. He says he invented it to punish homosexuals, Nazis, and short people. It's short people that he's really afraid of. He's sure that all the short people on TV are talking about him. He thinks that short people are conspiring to make him look like a Republican. Eduardo frequently gets in arguments with people and is emotionally volatile. His grooming is poor, but he says it's okay because he's the secretary of state.

   Preliminary diagnosis: _____

3. Margaret has hardly gotten out of bed for weeks, although she's troubled by insomnia. She doesn't feel like eating and has absolutely no energy. She feels dejected, discouraged, spiritless, and apathetic. Friends stop by to try to cheer her up, but she tells them not to waste their time on "pond scum."

   Preliminary diagnosis: _____

comprehensive, well-coordinated, quality care is initiated promptly, higher recovery rates in the vicinity of 50% have been found (Hopper et al., 2007; Liberman & Kopelowicz, 2005). Thus, the outlook for schizophrenia may not need to be as pervasively negative as it has been.

Etiology of Schizophrenia 11c

You can probably identify, at least to some extent, with people who suffer from mood disorders, somatoform disorders, and anxiety disorders. You can probably imagine events that could unfold that might leave you struggling with depression, grappling with anxiety, or worrying about your physical health. But what could possibly have led Ed to believe that he had been fighting space wars and vampires? What could account for Sylvia's thinking that she was Joan of Arc or that she had dictated the hobbit novels to Tolkien? As mystifying as these delusions may seem, you'll see that the etiology of schizophrenic disorders is not all that different from the etiology of other psychological disorders. We'll begin our discussion by examining the matter of genetic vulnerability.

Genetic Vulnerability 11c

Evidence is plentiful that hereditary factors play a role in the development of schizophrenic disorders (Sullivan et al., 2006; Tsuang, Glatt, & Faraone, 2003). For instance, in twin studies, concordance rates average around 48% for identical twins, in comparison to about 17% for fraternal twins (Gottesman, 1991, 2001). Studies also indicate that a child born to two schizophrenic parents has about a 46% probability of developing a schizophrenic disorder (as compared to the probability in the general population of about 1%). These and other findings that demonstrate the genetic roots of schizophrenia are summarized in **Figure 14.18**. Overall, the picture is similar to that seen for mood disorders. Several converging lines of evidence indicate that some people inherit a polygenically transmitted *vulnerability* to schizophrenia (Riley & Kendler, 2005; Schneider & Deldin, 2001). Although some theorists suspect that genetic factors may account for as much as two-thirds of the variability in susceptibility to schizophrenia, genetic mapping studies have made little progress in identifying the specific genes at work (Crow, 2007; Walker & Tessner, 2008).

Neurochemical Factors 11c

Like mood disorders, schizophrenic disorders appear to be accompanied by changes in the activity of one or more neurotransmitters in the brain (Patel, Pinals, & Breier, 2003). The *dopamine hypothesis* asserts that excess dopamine activity is the neurochemical basis for schizophrenia, as presented in **Figure 14.19** on the next page. This hypothesis makes sense because most of the drugs that are useful in the treatment of schizophrenia are known to dampen dopamine activity in the brain (Javitt & Laruelle, 2006; Tamminga & Carlsson, 2003). However, the evidence linking schizophrenia to high dopamine levels is riddled with inconsistencies, complexities, and interpretive problems (Abi-Dargham, 2004). Researchers are currently exploring how interactions between the dopamine and serotonin neurotransmitter systems may contribute to schizophrenia (Patel et al., 2003).
Recent research has suggested that marijuana use during adolescence may help precipitate schizophrenia in young people who have a genetic vulnerability to the disorder (Compton, Goulding, & Walker, 2007; Degenhardt & Hall, 2006). This unexpected finding has generated considerable debate about whether and how cannabis might contribute to the emergence of schizophrenia (Castle, 2008; DeLisi, 2008). The current thinking is that the key chemical ingredient in marijuana (THC) may amplify neurotransmitter activity in dopamine circuits (Degenhardt & Hall, 2006; Di Forti et al., 2007). The data on this issue are still preliminary, and more research will be needed to fully understand the association between marijuana use and schizophrenia.

Structural Abnormalities in the Brain 11c

For decades, studies have suggested that individuals with schizophrenia exhibit a variety of deficits in attention, perception, and information processing (Gold & Green, 2005; Keefe & Eesley, 2006). Impairments in working (short-term) memory are

Relationship	Genetic relatedness	Concordance rate (%) (lifetime risk)
Identical twin	100%	
Offspring of two schizophrenic patients	50% with each parent	
Fraternal twin	50%	
Offspring of one schizophrenic patient	50%	
Sibling	50%	
Nephew or niece	25%	
Unrelated person in the general population	0%	

Figure 14.18

Genetic vulnerability to schizophrenic disorders. Relatives of schizophrenic patients have an elevated risk for schizophrenia. This risk is greater among closer relatives. Although environment also plays a role in the etiology of schizophrenia, the concordance rates shown here suggest that there must be a genetic vulnerability to the disorder. These concordance estimates are based on pooled data from 40 studies conducted between 1920 and 1987. (Data from Gottesman, 1991)

Figure 14.19

The dopamine hypothesis as an explanation for schizophrenia. Decades of research have implicated overactivity at dopamine synapses as a key cause of schizophrenic disorders. However, the evidence on the exact mechanisms underlying this overactivity, which is summarized in this graphic, is complex and open to debate. Recent hypotheses about the neurochemical bases of schizophrenia go beyond the simple assumption that dopamine activity is increased. For example, one theory posits that schizophrenia may be accompanied by decreased dopamine activity in one area of the brain (the prefrontal cortex) and increased activity or dysregulation in other areas of the brain (Egan & Hyde, 2000). Moreover, abnormalities in other neurotransmitter systems may also contribute to schizophrenia.

1 Drugs that increase dopamine release can create or worsen the symptoms of schizophrenia. Hence, scientists originally attributed overactivity at dopamine synapses to excessive synthesis and release of dopamine. However, research eventually undermined this view.

2 Overactivity at dopamine synapses in schizophrenia could be due to an overabundance of dopamine receptor sites. Scientists have discovered five subtypes of dopamine receptor sites, and evidence suggests that one of these subtypes (D_2) is present in increased numbers in schizophrenic patients. However, the significance of this finding is debated because the elevation in D_2 receptor sites may be attributable to long-term treatment with antipsychotic drugs.

3 Traditional antipsychotic drugs that are effective in the treatment of schizophrenia appear to work by binding to dopamine receptor sites where they block normal dopamine activity. The clinical efficacy of various antipsychotic drugs correlates with their ability to block activity at D_2 receptor sites.

especially prominent (Silver et al., 2003). These cognitive deficits suggest that schizophrenic disorders may be caused by neurological defects. Until recent decades this theory was based more on speculation than on actual research. Now, however, advances in brain-imaging technology have yielded mountains of intriguing data. The most reliable finding is that CT scans and MRI scans (see Chapter 3) suggest an association between enlarged brain ventricles (the hollow, fluid-filled cavities in the brain depicted in **Figure 14.20**) and schizophrenic disturbance (Belger & Dichter, 2006). Enlarged ventricles are assumed to reflect the degeneration of nearby brain tissue. The significance of enlarged ventricles is hotly debated, however. This structural deterioration (or failure to develop) could be a *consequence* of schizophrenia, or it could be a contributing *cause* of the illness.

Brain-imaging studies have also uncovered structural and metabolic abnormalities in the frontal lobes of individuals with schizophrenia. Although the research results are not entirely consistent, schizophrenia appears to be associated with smaller size and reduced metabolic activity in areas of the prefrontal

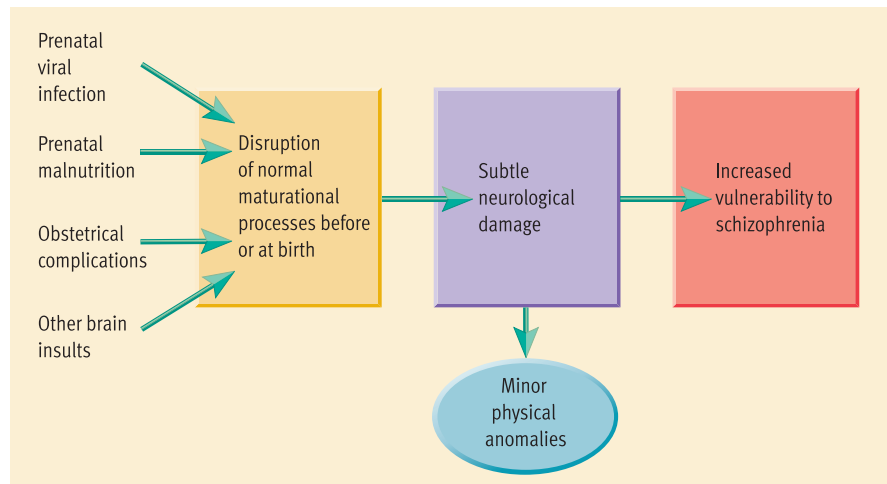
Figure 14.20

Schizophrenia and the ventricles of the brain. Cerebrospinal fluid (CSF) circulates around the brain and spinal cord. The hollow cavities in the brain filled with CSF are called ventricles. The four ventricles in the human brain are depicted here. Recent studies with CT scans and MRI scans suggest that an association exists between enlarged ventricles in the brain and the occurrence of schizophrenic disturbance.

cortex (Fowles, 2003). Scientists are also intrigued by the fact that a major dopamine pathway runs through the area in the prefrontal cortex where metabolic abnormalities have been found. A connection may exist between the abnormal dopamine activity implicated in schizophrenia and the dysfunctional metabolic activity seen in this area of the prefrontal cortex (Conklin & Iacono, 2002). Although the research on the prefrontal cortex is intriguing, Ho, Black, and Andreasen (2003) caution that the neural correlates of schizophrenia are complex and that the disease is not likely to be caused by "a single abnormality in a single region of the brain" (p. 408).

The Neurodevelopmental Hypothesis   11c

Several relatively new lines of evidence have led to the emergence of the *neurodevelopmental hypothesis* of schizophrenia, which asserts that schizophrenia is caused in part by various disruptions in the normal maturational processes of the brain before or at birth (Brown, 1999). According to this hypothesis, insults to the brain during sensitive phases of prenatal development or during birth can cause subtle neurological damage that elevates individuals' vulnerability to schizophrenia years later in adolescence and early adulthood (see **Figure 14.21**). What are the sources of these early insults to the brain? Thus far, research has mostly focused on viral infections or malnutrition during prenatal development and obstetrical complications during the birth process.

The evidence on viral infections has been building since Sarnoff Mednick and his colleagues (1988) discovered an elevated incidence of schizophrenia among individuals who were in their second trimester of prenatal development during a 1957 influenza epidemic in Finland. Several subsequent studies in other locations have also found a link between exposure to influenza during the second trimester and increased prevalence of schizophrenia (Brown et al., 2004). Another study, which investigated the possible impact of prenatal malnutrition, found an elevated incidence of schizophrenia in a cohort of people who were prenatally exposed to a severe famine in 1944–45 resulting from a Nazi blockade of food deliveries in the Netherlands during World War II (Susser et al., 1996). A recent study looked at a new source of disruption during prenatal development: severe maternal stress. The study found an elevated prevalence of schizophrenia among the offspring of women who suffered severe stress during their pregnancy (Khashan et al., 2008). Other research has shown that schizophrenic patients are more likely than control subjects to have a history of obstetrical complications (Kelly et al., 2004; Murray & Bramon, 2005). Finally, research suggests that minor physical anomalies (slight anatomical defects of the head, hands, feet, and face) that would be consistent with prenatal neurological damage are more common among people with schizophrenia than among others (McNeil, Canton-Graae, & Ismail, 2000; Schiffman et al., 2002). Collectively, these diverse studies argue for a relationship between early neurological trauma and a predisposition to schizophrenia (Mednick et al., 1998).


Expressed Emotion   11c

Studies of expressed emotion have primarily focused on how this element of family dynamics influences the *course* of schizophrenic illness, after the onset of the disorder (Leff & Vaughn, 1985). *Expressed emotion (EE) is the degree to which a relative of a patient displays highly critical or emotionally overinvolved attitudes toward the patient.* Audiotaped interviews of relatives' communication are carefully evaluated for critical comments, hostility toward the patient, and excessive emotional involvement (overprotective, overconcerned attitudes) (Hooley, 2004).

Studies show that a family's expressed emotion is a good predictor of the course of a schizophrenic patient's illness (Hooley, 2007). After release from a hospital, people with schizophrenia who return to a family high in expressed emotion show relapse rates about three times that of patients who return to a family low in expressed emotion (see **Figure 14.22** on the next page; Hooley & Hiller, 1998). Part of the problem for patients returning to homes high in expressed emotion is that their families are probably sources of more *stress* than of *social support*

Figure 14.21
The neurodevelopmental hypothesis of schizophrenia. Recent findings have suggested that insults to the brain sustained during prenatal development or at birth may disrupt crucial maturational processes in the brain, resulting in subtle neurological damage that gradually becomes apparent as youngsters develop. This neurological damage is believed to increase both vulnerability to schizophrenia and the incidence of minor physical anomalies (slight anatomical defects of the head, face, hands, and feet).

Figure 14.22
Expressed emotion and relapse rates in schizophrenia. Schizophrenic patients who return to a home that is high in expressed emotion have higher relapse rates than those who return to a home low in expressed emotion. Thus, unhealthy family dynamics can influence the course of schizophrenia. (Data adapted from Leff & Vaughn, 1981)

Two-year relapse rate (%)

Expressed emotion in patient's family

High

Low
(Cutting & Docherty, 2000). Although the effects of expressed emotion have been explored primarily with schizophrenic patients, accumulating evidence suggests that high levels of expressed emotion also foster higher relapse rates for patients suffering from mood and anxiety disorders (Hooley, 2004, 2007).

Precipitating Stress   11c

Most theories of schizophrenia assume that stress plays a key role in triggering schizophrenic disorders (Walker & Tessner, 2008). According to this notion, various biological and psychological factors influence individuals' *vulnerability* to schizophrenia. High stress may then serve to precipitate a schizophrenic disorder in someone who is vulnerable. Research indicates that high stress can also trigger relapses in patients who have made progress toward recovery (Walker, Mittal, & Tessner, 2008).

Schizophrenia is the last of the major, Axis I diagnostic categories that we will consider. We'll complete our overview of various types of abnormal behavior with a brief look at the personality disorders. These disorders are recorded on Axis II in the DSM classification system.

REVIEW of Key Points

14.16 Disturbed, irrational thought processes, including delusions, are the defining feature of schizophrenic disorders. Schizophrenia is also characterized by deterioration of everyday adaptive behavior, auditory hallucinations, and disturbed emotion.

14.17 Schizophrenic disorders are classified as paranoid, catatonic, disorganized, or undifferentiated. A classification scheme based on the predominance of positive versus negative symptoms has been proposed, but has not supplanted the traditional classification system. Schizophrenic disorders usually emerge during adolescence or young adulthood. The course of the disorder tends to involve chronic deterioration for many patients, but with prompt, effective care recovery is possible.

14.18 Twin studies and other research show that some people inherit a genetic vulnerability to schizophrenia. The dopamine hypothesis asserts that excess dopamine activity is the neurochemcial basis for schizophrenia. The dopamine hypothesis may explain why recent research has uncovered a link between marijuana use and vulnerability to schizophrenia.

14.19 Structural abnormalities in the brain, such as enlarged ventricles, are associated with schizophrenia, but their causal significance is unclear. The neurodevelopmental hypothesis of schizophrenia asserts that schizophrenia is attributable to disruptions in the normal maturational processes of the brain before or at birth that are caused by prenatal viral infections, obstetrical complications, and other insults to the brain.

14.20 Patients who come from homes high in expressed emotion have elevated relapse rates, suggesting that unhealthy family dynamics play a role in schizophrenia. High stress may also contribute to the onset of schizophrenia.

Personality Disorders

Key Learning Goals

14.21 Discuss the nature of personality disorders and problems with the diagnosis of such disorders.

14.22 Describe the antisocial personality disorder, and discuss its etiology.

We have seen repeatedly that it is often difficult to draw that imaginary line between healthy and disordered behavior. This is especially true in the case of personality disorders, most of which are milder disturbances in comparison to most of the Axis I disorders. *Personality disorders* **are a class of disorders marked by extreme, inflexible personality traits that cause subjective distress or impaired social and occupational functioning.** Essentially, people with these disorders display certain personality traits to an excessive degree and in rigid ways that undermine their adjustment. Personality disorders usually emerge during late childhood or adoles-

cence and often continue throughout adulthood. It is difficult to estimate the prevalence of these subtle disorders, but it is clear that they are common (Mattia & Zimmerman, 2001).

DSM-IV lists ten personality disorders, which are grouped into three related clusters: anxious-fearful, odd-eccentric, and dramatic-impulsive. These disorders are described briefly in Table 14.2. If you examine this table, you will find a diverse collection of maladaptive personality syndromes. You may also notice that some personality disorders essentially are milder versions of more severe Axis I disorders. For example, obsessive compulsive personality dis-

Table 14.2 Personality Disorders

Cluster	Disorder	Description	% Male/% Female
Anxious/fearful	Avoidant personality disorder	Excessively sensitive to potential rejection, humiliation, or shame; socially withdrawn in spite of desire for acceptance from others	50/50
	Dependent personality disorder	Excessively lacking in self-reliance and self-esteem; passively allowing others to make all decisions; constantly subordinating own needs to others' needs	31/69
	Obsessive-compulsive personality disorder	Preoccupied with organization, rules, schedules, lists, trivial details; extremely conventional, serious, and formal; unable to express warm emotions	50/50
Odd/eccentric	Schizoid personality disorder	Defective in capacity for forming social relationships; showing absence of warm, tender feelings for others	78/22
	Schizotypal personality disorder	Showing social deficits and oddities of thinking, perception, and communication that resemble schizophrenia	55/45
	Paranoid personality disorder	Showing pervasive and unwarranted suspiciousness and mistrust of people; overly sensitive; prone to jealousy	67/33
Dramatic/impulsive	Histrionic personality disorder	Overly dramatic; tending to exaggerated expressions of emotion; egocentric, seeking attention	15/85
	Narcissistic personality disorder	Grandiosely self-important; preoccupied with success fantasies; expecting special treatment; lacking interpersonal empathy	70/30
	Borderline personality disorder	Unstable in self-image, mood, and interpersonal relationships; impulsive and unpredictable	38/62
	Antisocial personality disorder	Chronically violating the rights of others; failing to accept social norms, to form attachments to others, or to sustain consistent work behavior; exploitive and reckless	82/18

Source: Estimated gender ratios from Millon (1981).

order is a milder version of obsessive-compulsive disorder, and the schizoid and schizotypal personality disorders are milder cousins of schizophrenic disorders. Some personality disorders are more common in men and some in women, as the figures in the far right column of the table indicate.

Diagnostic Problems

Many critics have argued that the personality disorders overlap too much with Axis I disorders and with each other (Clark, 2007). The extent of this problem was documented in a study by Leslie Morey (1988). Morey reviewed the cases of 291 patients who had received a specific personality disorder diagnosis to see how many could have met the criteria for any of the other personality disorders. Morey found massive overlap among the diagnoses. For example, among patients with a diagnosis of histrionic personality disorder, 56% also qualified for a borderline disorder, 54% for a narcissistic disorder, 32% for an avoidant disorder, and 30% for a dependent disorder. Clearly, there are fundamental problems with Axis II as a classification system (Tyrer et al., 2007; Widiger, 2007). The overlap among the personality disorders makes it extremely difficult to achieve reliable diagnoses. Doubts have also been raised about the decision to place personality disorders on a sepa-

rate axis, as there does not appear to be any fundamental distinction between personality disorders and Axis I disorders (Krueger, 2005).

In light of these problems, a variety of theorists have questioned the wisdom of the current *categorical approach* to describing personality disorders, which assumes (incorrectly, they argue) that people can reliably be placed in discontinuous (nonoverlapping) diagnostic categories (Verheul, 2005; Widiger & Trull, 2007). These theorists argue instead for a *dimensional approach,* which would describe personality disorders in terms of how people score on a limited number of continuous personality dimensions. The practical logistics of using a dimensional approach to describe personality disorders are formidable, and experts note that the categorical approach better reflects how clinicians think about pathology (Phillips, Yen, & Gunderson, 2003). In any event, vigorous debate about the classification of personality disorders is likely to continue as researchers grapple with how to move from DSM-IV to DSM-V.

The difficulties involved in the diagnosis of personality disorders have clearly hindered research on their etiology and prognosis. The only personality disorder that has a long history of extensive research is the antisocial personality disorder, which we examine next.

Antisocial Personality Disorder

Antisocial personality disorder has a misleading name. The antisocial designation does *not* mean that people with this disorder shun social interaction. In fact, rather than shrinking from social interaction, many such individuals are sociable, friendly, and superficially charming. People with this disorder are *antisocial* in that they choose to *reject widely accepted social norms* regarding moral principles and behavior.

Description

People with antisocial personalities chronically violate the rights of others. They often use their social charm to cultivate others' liking or loyalty for purposes of exploitation. **The *antisocial personality disorder* is marked by impulsive, callous, manipulative, aggressive, and irresponsible behavior that reflects a failure to accept social norms.** Since they haven't accepted the social norms they violate, people with antisocial personalities rarely feel guilty about their transgressions. Essentially, they lack an adequate conscience. The antisocial personality disorder occurs much more frequently among males than females. Studies suggest that it is a moderately common disorder, seen in roughly 3%–6% of males and about 1% of females (Widiger & Mullins, 2003).

Many people with antisocial personalities get involved in illegal activities. Moreover, antisocial personalities tend to begin their criminal careers at an early age, to commit offenses at a relatively high rate, and to be versatile offenders who get involved in many types of criminal activity (Douglas, Vincent, & Edens, 2006; Hare, 2006; Porter & Porter, 2007). However, many people with antisocial personalities keep their exploitive, amoral behavior channeled within the boundaries of the law. Such people may even enjoy high status in our society (Babiak & Hare, 2006; Hall & Benning, 2006). In other words, the concept of the antisocial personality disorder can apply to cut-throat business executives, scheming politicians, unprincipled lawyers, and money-hungry evangelists, as well as to con artists, drug dealers, thugs, burglars, and petty thieves.

People with antisocial personalities exhibit quite a variety of maladaptive traits (Hare, 2006; Hare & Neumann, 2008). Among other things, they rarely experience genuine affection for others. However, they may be skilled at faking affection so they can exploit people. Sexually, they are predatory and promiscuous. They also tend to be irresponsible and impulsive. They can tolerate little frustration, and they pursue immediate gratification. These charac-

teristics make them unreliable employees, unfaithful spouses, inattentive parents, and undependable friends. Many people with antisocial personalities have a checkered history of divorce, child abuse, and job instability. The picture does tend to improve as those with antisocial personalities become middle-aged. One study that followed antisocial men into their 50s found substantial improvement in 58% of the subjects (Black, 2001).

Etiology

Many theorists believe that biological factors contribute to the development of antisocial personality disorders. Various lines of evidence suggest a genetic predisposition toward these disorders (Moffitt, 2005; Waldman & Rhee, 2006). A review of twin studies found an average concordance rate of 67% for identical twins in comparison to 31% for fraternal twins (Black, 2001). These findings are consistent with a fairly strong genetic vulnerability to the disorder. Many observers have noted that people with antisocial personalities lack the inhibitions that most of us have about violating moral standards. Their lack of inhibitions prompted Hans Eysenck (1982) to theorize that such people might inherit relatively sluggish autonomic nervous systems, leading to slow acquisition of inhibitions through classical conditioning. The notion that antisocial personalities exhibit underarousal has received some support (Raine, 1997), but the findings have been inconsistent (Blackburn, 2006), and some studies have suggested the opposite—that *overarousal* may promote antisocial behavior (Hart, Eisenberg, & Valiente, 2007). Part of the problem in this area of research may be that arousal can be quantified in a great many different ways.

Efforts to relate psychological factors to antisocial behavior have emphasized inadequate socialization in dysfunctional family systems (Farrington, 2006; Sutker & Allain, 2001). It's easy to envision how antisocial traits could be fostered in homes where parents make haphazard or halfhearted efforts to socialize their children to be respectful, truthful, responsible, unselfish, and so forth. Consistent with this idea, studies find that individuals with antisocial personalities tend to come from homes where discipline is erratic or ineffective or where they experience physical abuse and neglect (Luntz & Widom, 1994; Widom, 1997). Such people are also more likely to emerge from families where one or both parents exhibit antisocial traits (Black, 2001). These parents presumably model exploitive, amoral behaviors, which their children acquire through observational learning.

Psychological Disorders and the Law

Societies use laws to enforce their norms regarding appropriate behavior. Given this function, the law in our society has something to say about many issues related to abnormal behavior. In this section we examine the concepts of insanity and involuntary commitment.

Insanity

Insanity is *not* a diagnosis; it's a legal concept. **Insanity is a legal status indicating that a person cannot be held responsible for his or her actions because of mental illness.** Why is this an issue in the courtroom? Because criminal acts must be intentional. The law reasons that people who are "out of their mind" may not be able to appreciate the significance of what they're doing. The insanity defense is used in criminal trials by defendants who admit that they committed the crime but claim that they lacked intent.

No simple relationship exists between specific diagnoses of mental disorders and court findings of insanity. The vast majority of people with diagnosed psychological disorders would *not* qualify as insane. The people most likely to qualify are those troubled by severe disturbances that display delusional behavior. The courts apply various rules in making judgments about a defendant's sanity, depending on the jurisdiction (Simon, 2003). According to one widely used rule, called the *M'naghten rule, insanity exists when a mental disorder makes a person unable to distinguish right from wrong.* As you can imagine, evaluating insanity as defined in the M'naghten rule can be difficult for judges and jurors, not to mention the psychologists and psychiatrists who are called into court as expert witnesses.

Although highly publicized and controversial, the insanity defense is actually used less frequently and less successfully than widely believed (see **Figure 14.23**). One study found that the general public estimates that the insanity defense is used in 37% of felony cases, when in fact it is used in less than 1% (Silver, Cirincione, & Steadman, 1994). Another study of over 60,000 indictments in Baltimore found that only 190 defendants (0.31%) pleaded insanity, and of these, only 8 were successful (Janofsky et al., 1996).

Involuntary Commitment

The issue of insanity surfaces only in *criminal* proceedings. Far more people are affected by *civil* proceedings relating to involuntary commitment. **In involuntary commitment people are hospitalized in psychiatric facilities against their will.** What are the grounds for such a dramatic action? They vary some from state to state. Generally, people are subject to involuntary commitment when mental health professionals and legal authorities believe that a mental disorder makes them (1) dangerous to themselves (usually suicidal), (2) dangerous to others (potentially violent), or (3) in need of treatment (applied in cases of severe disorientation). In emergency situations psychologists and psychiatrists can authorize *temporary* commitment, usually for 24 to 72 hours. Orders for long-term involuntary commitment are

David Willshire's Forensic Psychology and Psychiatry Links

This site's webmaster, a senior psychologist at Australia's Victorian Institute of Forensic Mental Health, has brought together a large set of annotated links on all aspects of forensic matters—that is, how the law and criminal justice system interact with psychology and psychiatry.

Figure 14.23
The insanity defense: Public perceptions and actual realities. Silver, Cirincione, and Steadman (1994) collected data on the general public's beliefs about the insanity defense and the realities of how often it is used and how often it is successful (based on a large-scale survey of insanity pleas in eight states). Because of highly selective media coverage, dramatic disparities are seen between public perceptions and actual realities, as the insanity defense is used less frequently and less successfully than widely assumed.

Disruption of normal maturational processes before or at birth

Subtle neurological damage

Increased vulnerability to schizophrenia
The neurodevelopmental hypothesis: Insults to the brain sustained during prenatal development or at birth may disrupt maturational processes in the brain resulting in elevated vulnerability to schizophrenia.
Seung-Hui Cho, who gunned down 32 people at Virginia Tech in April of 2007, had a history of mental illness and showed many signs of psychological deterioration in the months leading up to the massacre. Given his struggles with psychological disturbance, many people were baffled about why he had not been subjected to involuntary commitment. But commitment proceedings based on his overt, known behavior prior to the murders (a couple of stalking incidents and some angry, violent class essays) probably would have failed. What most people do not understand is that laws in the United States generally set the bar very high for involuntary commitment. Why? Because predictions of dangerousness are not very accurate and because our legal system is reluctant to incarcerate people for what they might do. Unfortunately, our conservative approach to involuntary commitment sometimes has tragic consequences.

usually set up for renewable six-month periods and can be issued by a court only after a formal hearing. Mental health professionals provide extensive input in these hearings, but the courts make the final decisions (Simon, 2005).

Most involuntary commitments occur because people appear to be *dangerous* to themselves or others. The difficulty, however, is in predicting dangerousness. Studies suggest that clinicians' short-term predictions about which patients are likely to become violent are only moderately accurate and that their long-term predictions of violent behavior are largely inaccurate (Simon, 2003; Stone, 1999). This inaccuracy in predicting dangerousness is unfortunate, because involuntary commitment involves the *detention* of people for what they *might* do in the future. Such detention goes against the grain of the American legal principle that people are *innocent until proven guilty*. The inherent difficulty in predicting dangerousness makes involuntary commitment a complex and controversial issue.

> **REVIEW of Key Points**
>
> **14.23** Insanity is a legal concept applied to people who cannot be held responsible for their actions because of mental illness. The insanity defense is used less frequently and less successfully than widely believed. When people appear to be dangerous to themselves or others, courts may rule that they are subject to involuntary commitment in a hospital.

Culture and Pathology

The legal rules governing insanity and involuntary commitment obviously are culture-specific. And we noted earlier that judgments of normality and abnormality are influenced by cultural norms and values. In light of these realities, would it be reasonable to infer that psychological disorders are culturally variable phenomena? Social scientists are sharply divided on the answer to this question. Some embrace a *relativistic view* of psychological disorders, whereas others subscribe to a *universalistic or pancultural view* (Tanaka-Matsumi, 2001). Theorists who embrace the *relativistic view* argue that the criteria of mental illness vary greatly across cultures and that there are no universal standards of normality and abnormality. According to the relativists, the DSM diagnostic system reflects an ethnocentric, Western, white, urban, middle- and upper-class cultural orientation

that has limited relevance in other cultural contexts. In contrast, those who subscribe to the *pancultural view* argue that the criteria of mental illness are much the same around the world and that basic standards of normality and abnormality are universal across cultures. Theorists who accept the pancultural view of psychopathology typically maintain that Western diagnostic concepts have validity and utility in other cultural contexts.

The debate about culture and pathology basically boils down to two specific issues: (1) Are the psychological disorders seen in Western societies found throughout the world? (2) Are the symptom patterns of mental disorders invariant across cultures? Let's briefly examine the evidence on these questions and then reconsider the relativistic and pancultural views of psychological disorders.

Are Equivalent Disorders Found Around the World?

Most investigators agree that the principal categories of serious psychological disturbance—schizophrenia, depression, and bipolar illness—are identifiable in all cultures (Tsai et al., 2001). Most behaviors that are regarded as clearly abnormal in Western culture are also viewed as abnormal in other cultures. People who are delusional, hallucinatory, disoriented, or incoherent are thought to be disturbed in all societies, although there are cultural disparities in exactly what is considered delusional or hallucinatory.

Cultural variations are more apparent in the recognition of less severe forms of psychological disturbance (Mezzich, Lewis-Fernandez, & Ruiperez, 2003). Additional research is needed, but relatively mild types of pathology that do not disrupt behavior in obvious ways appear to go unrecognized in many societies. Thus, syndromes such as generalized anxiety disorder, hypochondria, and narcissistic personality disorder, which are firmly established as diagnostic entities in the DSM, are viewed in some cultures as "run of the mill" difficulties and peculiarities rather than as full-fledged disorders.

Finally, researchers have discovered a small number of *culture-bound disorders* that further illustrate the diversity of abnormal behavior around the world (Griffith, Gonzalez, & Blue, 2003; Trujillo, 2005). **Culture-bound disorders are abnormal syndromes found only in a few cultural groups.** For example, *koro,* an obsessive fear that one's penis will withdraw into one's abdomen, is seen only among Chinese males in Malaya and several other regions of southern Asia. *Windigo,* which involves an intense craving for human flesh and fear that one will turn into a cannibal, is seen only among Algonquin Indian cultures. And until fairly recently, the eating disorder *anorexia nervosa,* discussed in this chapter's Personal Application, was largely seen only in affluent Western cultures.

Are Symptom Patterns Culturally Invariant?

Do the major types of psychological disorders manifest themselves in the same way around the world?

It depends to some extent on the disorder. The more a disorder has a strong biological component, the more it tends to be expressed in similar ways across varied cultures (Marsella & Yamada, 2007). Thus, the constellations of symptoms associated with schizophrenia and bipolar illness are largely the same across widely disparate societies (Draguns, 1980, 1990). However, even in severe, heavily biological disorders, cultural variations in symptom patterns are also seen (Mezzich et al., 2003). For example, delusions are a common symptom of schizophrenia in all cultures, but the specific delusions that people report are tied to their cultural heritage (Brislin, 1993). In technologically advanced societies, schizophrenic patients report that thoughts are being inserted into their minds through transmissions from electric lines, satellites, or microwave ovens. Victims of schizophrenia in less technological societies experience the same phenomenon but blame sorcerers or demons. Of the major disorders, symptom patterns are probably most variable for depression. For example, profound feelings of guilt and self-deprecation lie at the core of depression in Western cultures but are far less central to depression in many other societies. In non-Western cultures, depression tends to be expressed in terms of somatic symptoms, such as complaints of fatigue, headaches, and backaches, more than psychological symptoms, such as dejection and low self-esteem (Tsai et al., 2001; Young, 1997). These differences presumably occur because people learn to express symptoms of psychological distress in ways that are acceptable in their culture.

So, what can we conclude about the validity of the relativistic versus pancultural views of psychological disorders? Both views appear to have some merit. As we have seen in other areas of research, psychopathology is characterized by both cultural variance and invariance. Investigators have identified some universal standards of normality and abnormality and found considerable similarity across cultures in the syndromes that are regarded as pathological and in their patterns of symptoms. However, researchers have also discovered many cultural variations in the recognition, definition, and symptoms of various psychological disorders. Given this extensive variability, the relativists' concerns about the ethnocentric nature of the DSM diagnostic system seem well founded.

Key Learning Goals

14.26 Identify the four unifying themes highlighted in this chapter.

Multifactorial Causation

Heredity and Environment

Sociohistorical Context

Cultural Heritage

Reflecting on the Chapter's Themes

Our examination of abnormal behavior and its roots has highlighted four of our organizing themes: multifactorial causation, the interplay of heredity and environment, the sociohistorical context in which psychology evolves, and the influence of culture on psychological phenomena.

We can safely assert that every disorder described in this chapter has multiple causes. The development of mental disorders involves an interplay among a variety of psychological, biological, and social factors. We also saw that most psychological disorders depend on an interaction of genetics and experience. This interaction shows up most clearly in the *stress-vulnerability models* for mood disorders and schizophrenic disorders (see **Figure 14.24**). *Vulnerability* to these disorders seems to depend primarily on heredity, whereas stress is largely a function of environment. According to stress-vulnerability theories, disorders emerge when high vulnerability intersects with high stress. A high biological vulner-

ability may not be converted into a disorder if a person's stress is low. Similarly, high stress may not lead to a disorder if vulnerability is low. Thus, the impact of heredity depends on the environment, and the effect of environment depends on heredity.

This chapter also demonstrated that psychology evolves in a sociohistorical context. We saw that modern conceptions of normality and abnormality are largely shaped by empirical research, but social trends, economic necessities, and political realities also play a role. Finally, our discussion of psychological disorders showed once again that psychological phenomena are shaped to some degree by cultural parameters. Although some standards of normality and abnormality transcend cultural boundaries, cultural norms influence many aspects of psychopathology. Indeed, the influence of culture will be apparent in our upcoming Personal Application on eating disorders. These disorders are largely a creation of modern, affluent, Western culture.

REVIEW of Key Points

14.26 This chapter highlighted four of our unifying themes, showing that behavior is governed by multiple causes, that heredity and environment jointly influence mental disorders, that psychology evolves in a sociohistorical context, and that pathology is characterized by both cultural variance and invariance.

Figure 14.24

The stress-vulnerability model of schizophrenia. Multifactorial causation is readily apparent in current theories about the etiology of schizophrenic disorders. A variety of biological factors and personal history factors influence one's vulnerability to the disorder, which interacts with the amount of stress one experiences. Schizophrenic disorders appear to result from an intersection of high stress and high vulnerability.

Environmental factors in present
Deficient school performance
Work troubles
Rejection from others
Family conflicts
Low social support

Environmental factors in personal history
Communication deviance
Negative expressed emotion
Distorted, unhealthy family relations
Development of poor social skills
Development of poor coping skills

Biological factors
Genetic predisposition
Disruption of neurological development
Neurochemical irregularities
Structural and metabolic abnormalities in the brain

Stress

Vulnerability

Intersection of high stress and high vulnerability

Onset of schizophrenic disorder

Increased stress?
e.g., increase in family-expressed emotion; increased difficulty in finding job because of psychiatric label

Increased vulnerability?
e.g., atrophy of coping skills during hospitalization; self-fulfilling prophecy of psychiatric label

Understanding Eating Disorders

Answer the following "true" or "false."

___ 1 Although they have only attracted attention in recent years, eating disorders have a long history and have always been fairly common.

___ 2 People with anorexia nervosa are much more likely to recognize that their eating behavior is pathological than people suffering from bulimia nervosa are.

___ 3 The prevalence of eating disorders is twice as high in women as it is in men.

___ 4 The binge-and-purge syndrome seen in bulimia nervosa is not common in anorexia nervosa.

All of the above statements are false, as you will see in this Personal Application. The psychological disorders that we discussed in the main body of the chapter have largely been recognized for centuries, and most of them are found in one form or another in all cultures and societies. Eating disorders present a sharp contrast to this picture; they have only been recognized relatively recently and have largely been confined to affluent, Westernized cultures (G. F. M. Russell, 1995; Szmukler & Patton, 1995). In spite of these fascinating differences, eating disorders have much in common with traditional forms of pathology.

Description

Although most people don't seem to take eating disorders as seriously as other types of psychological disorders, you will see that they are dangerous and debilitating (Thompson, Roehrig, & Kinder, 2007). No psychological disorder is associated with a greater elevation in mortality (Striegel-Moore & Bulik, 2007). ***Eating disorders are severe disturbances in eating behavior characterized by preoccupation with weight and unhealthy efforts to control weight.*** In DSM-IV, two sometimes overlapping syndromes are recognized: *an-orexia nervosa* and *bulimia nervosa.* A third syndrome, called *binge-eating disorder,* is described in the appendix of DSM-IV as a potential new disorder, pending further study. We will devote our attention in this Application to the two established eating disorders, but we will briefly outline the symptoms of this new disorder as well.

Anorexia Nervosa

Anorexia nervosa involves intense fear of gaining weight, disturbed body image, refusal to maintain normal weight, and use of dangerous measures to lose weight. Two subtypes have been observed (Herzog & Delinski, 2001). In *restricting type anorexia nervosa,* people drastically reduce their intake of food, sometimes literally starving themselves. In *binge-eating/purging type anorexia nervosa,* individuals attempt to lose weight by forcing themselves to vomit after meals, by misusing laxatives and diuretics, and by engaging in excessive exercise.

Eating disorders have become distressingly common among young women in Western cultures. No matter how frail they become, people suffering from anorexia insist that they are too fat.

Key Learning Goals

14.27 Describe the subtypes, history, and prevalence of eating disorders.

14.28 Outline how genetic factors, personality, culture, family dynamics, and disturbed thinking contribute to eating disorders.

People with both types suffer from disturbed body image. No matter how frail and emaciated they become, they insist that they are too fat. Their morbid fear of obesity means that they are never satisfied with their weight. If they gain a pound or two, they panic. The only thing that makes them happy is to lose more weight. The common result is a relentless decline in body weight; people entering treatment for anorexia nervosa are typically 25%–30% below their normal weight (Hsu, 1990). Because of their disturbed body image, people suffering from anorexia generally do *not* appreciate the maladaptive quality of their behavior and rarely seek treatment on their own. They are typically coaxed or coerced into treatment by friends or family members who are alarmed by their appearance.

Anorexia nervosa eventually leads to a cascade of medical problems, including *amenorrhea* (a loss of menstrual cycles in women), gastrointestinal problems, low blood pressure, *osteoporosis* (a loss of bone density), and metabolic disturbances that can lead to cardiac arrest or circulatory collapse (Pomeroy & Mitchell, 2002; Walsh, 2003). Anorexia is a serious illness that leads to death in 5%–10% of patients (Steinhausen, 2002).

Bulimia Nervosa

Bulimia nervosa involves habitually engaging in out-of-control overeating followed by unhealthy compensatory efforts, such as self-induced vomiting, fasting, abuse of laxatives and diuretics, and excessive exercise. The eating binges are usually carried out in secret and are followed by intense guilt and concern about gaining weight. These feelings motivate ill-advised strategies to undo the effects of the

overeating. However, vomiting prevents the absorption of only about half of recently consumed food, and laxatives and diuretics have negligible impact on caloric intake, so people suffering from bulimia nervosa typically maintain a reasonably normal weight (Beumont, 2002; Kaye et al., 1993). Medical problems associated with bulimia nervosa include cardiac arrythmias, dental problems, metabolic deficiencies, and gastrointestinal problems (Halmi, 2002, 2003). Bulimia often coexists with other psychological disturbances, including depression, anxiety disorders, and substance abuse (Hudson et al., 2007).

Obviously, bulimia nervosa shares many features with anorexia nervosa, such as a morbid fear of becoming obese, preoccupation with food, and rigid, maladaptive approaches to controlling weight that are grounded in naive all-or-none thinking. The close relationship between the disorders is demonstrated by the fact that many patients who initially develop one syndrome cross over to display the other syndrome (Tozzi et al., 2005). However, the two syndromes also differ in crucial ways. First and foremost, bulimia is a much less life-threatening condition. Second, although their appearance is usually more "normal" than that seen in anorexia, people with bulimia are much more likely to recognize that their eating behavior is pathological and are more likely to cooperate with treatment (Striegel-Moore, Silberstein, & Rodin, 1993; Guarda et al., 2007).

Binge-Eating Disorder

A surprising number of people who exhibit disordered eating do not fit neatly into the anorexia or bulimia categories, which is why a third category has been proposed. *Binge-eating disorder* **involves distress-inducing eating binges that are not accompanied by the purging, fasting, and excessive exercise seen in bulimia.** Obviously, this syndrome resembles bulimia, but it is a less severe disorder. Still, this disorder creates great distress, as people tend to be disgusted by their bodies and distraught about their overeating. People with binge-eating disorder are frequently overweight. Their excessive eating is often triggered by stress

(Gluck, 2006). Research suggests that this comparatively mild syndrome may be more common than anorexia or bulimia (Hudson et al., 2007). Given the research that has been compiled since DSM-IV was released in 1994, it appears likely that binge-eating disorder will be recognized as an independent disorder in the forthcoming DSM-V (Striegel-Moore & Franko, 2008).

History and Prevalence

Historians have been able to track down descriptions of anorexia nervosa that date back centuries, so the disorder is *not* entirely new, but anorexia nervosa did not become a common affliction until the middle part of the 20th century (Vandereycken, 2002). Although binging and purging have a long history in some cultures, they were not part of pathological efforts to control weight, and bulimia nervosa appears to be a new syndrome that emerged gradually in the middle of the 20th century and was first recognized in the 1970s (G. F. M. Russell, 1997; Vandereycken, 2002).

Both disorders are a product of modern, affluent, Western culture, where food is generally plentiful and the desirability of being thin is widely endorsed. Until recently, these disorders were not seen outside of Western cultures (Hoek, 2002). However, advances in communication have exported Western culture to far-flung corners of the globe, and eating disorders have started showing up in many non-Western societies, especially affluent Asian countries (Becker & Fay, 2006; Lee & Katzman, 2002).

A huge gender gap is seen in the likelihood of developing eating disorders. About 90%–95% of individuals with eating disorders are female (Thompson & Kinder, 2003). This staggering discrepancy appears to be a result of cultural pressures rather than biological factors (Smolak & Murnen, 2001). Western standards of attractiveness emphasize slenderness more for females than for males, and women generally experience greater pressure to be physically attractive than men do (Strahan et al., 2008). Eating disorders mostly afflict *young* women. The typical age of onset is 14 to 18 for anorexia and 15 to 21 for bulimia (see **Figure 14.25**).

How common are eating disorders in Western societies? Studies of young women suggest that about 1% develop anorexia nervosa and about 2%–3% develop bulimia nervosa (Anderson & Yager, 2005). However, prevalence rates appear to be trending higher in more recent studies (Thompson et al., 2007). In some respects, these figures may only scratch the surface of the problem. Evidence suggests that as many as 20% of female college students may struggle with transient bulimic symptoms (Anderson & Yager, 2005). And recent community surveys suggest that there may be more undiagnosed eating disorders among men than generally appreciated (Hudson et al., 2007).

Etiology of Eating Disorders

Like other types of psychological disorders, eating disorders are caused by multiple determinants that work interactively. Let's take a brief look at some of the factors that contribute to the development of anorexia nervosa and bulimia nervosa.

Genetic Vulnerability

The evidence is not nearly as strong or complete as for many other types of psychopathology (such as anxiety, mood, and schizophrenic disorders), but some people may inherit a genetic vulnerability to eating disorders (Slof-Op't Landt et al., 2005). Studies show that relatives of patients with eating disorders have elevated rates of anorexia nervosa and bulimia nervosa (Bulik, 2004). Twin studies suggest that a genetic predisposition may be at work (Steiger, Bruce, & Israel, 2003).

Personality Factors

Certain personality traits may increase vulnerability to eating disorders. There are innumerable exceptions, but victims of anorexia nervosa tend to be obsessive, rigid, and emotionally restrained, whereas victims of bulimia nervosa tend to be impulsive, overly sensitive, and low in self-esteem (Anderluh et al., 2003; Wonderlich, 2002). Recent research also suggests that perfectionism is a risk factor for anorexia (Bulik et al., 2003; Halmi et al., 2000).
Figure 14.25

Age of onset for anorexia nervosa. Eating disorders tend to emerge during adolescence, as these data for anorexia nervosa show. This graph shows how age of onset was distributed in a sample of 166 female patients from Minnesota. As you can see, over half the patients experienced the onset of their illness before the age of 20, with vulnerability clearly peaking between the ages of 15 and 19. (Adapted from Lucas, et al., 1991)

Cultural Values

The contribution of cultural values to the increased prevalence of eating disorders can hardly be overestimated (Anderson-Fye & Becker, 2004; Striegel-Moore & Bulik, 2007). In Western society, young women are socialized to believe that they must be attractive, and to be attractive they must be as thin as the actresses and fashion models that dominate the media (Levine & Harrison, 2004). Thanks to this cultural milieu, many young women are dissatisfied with their weight, as the societal ideals promoted by the media are unattainable for most of them (Thompson & Stice, 2001). Unfortunately, in a portion of these women, the pressure to be thin, in combination with genetic vulnerability, family pathology, and other factors, leads to unhealthful efforts to control weight.

The Role of the Family

Quite a number of theorists emphasize how family dynamics can contribute to the development of anorexia and bulimia in young women (Haworth-Hoeppner, 2000). The principal issue appears to be that some mothers contribute to eating disorders simply by endorsing society's message that "you can never be too thin" and by modeling unhealthy dieting behaviors of their own (Francis & Birch, 2005). In conjunction with media pressures, this role modeling leads many daughters to internalize the idea that the thinner you are, the more attractive you are.

Cognitive Factors

Many theorists emphasize the role of disturbed thinking in the etiology of eating disorders (Williamson et al., 2001). For example, anorexic patients' typical belief that they are fat when they are really wasting away is a dramatic illustration of how thinking goes awry. Patients with eating disorders display rigid, all-or-none thinking and many maladaptive beliefs, such as "I must be thin to be accepted"; "If I am not in complete control, I will lose all control"; and "If I gain one pound, I'll go on to gain enormous weight." Additional research is needed to determine whether distorted thinking is a *cause* or merely a *symptom* of eating disorders.

REVIEW of Key Points

14.27 The principal eating disorders are anorexia nervosa and bulimia nervosa, with binge-eating disorder a proposed third syndrome. Anorexia and bulimia both lead to a cascade of medical problems, but anorexia is more dangerous. Both disorders are largely a product of affluent, Westernized culture that weren't recognized until the 20th century. Females account for 90%–95% of eating disorders. Among young women, about 1% develop anorexia nervosa and about 2%–3% develop bulimia nervosa, typically between the age of 15 to 20.

14.28 There appears to be a genetic vulnerability to eating disorders. Certain personality traits increase the vulnerability to eating disorders. Cultural pressures on young women to be thin clearly help to foster eating disorders. Families that endorse the idea that you can never be too thin can help to promote eating disorders. Rigid, disturbed thinking can also contribute to the development of these disorders.

Key Learning Goals

14.29 Understand how mental heuristics can distort estimates of cumulative and conjunctive probabilities.

Working with Probabilities in Thinking About Mental Illness

As you read about the various types of psychological disorders, did you think to yourself that you or someone you know was being described? On the one hand, there is no reason to be alarmed. The tendency to see yourself and your friends in descriptions of pathology is a common one, sometimes called the *medical students' disease* because beginning medical students often erroneously believe that they or their friends have whatever diseases they are currently learning about. On the other hand, realistically speaking, it *is* quite likely that you know *many* people with psychological disorders because—as you learned in the main body of the chapter—the likelihood of anyone having at least one DSM disorder is estimated to be about 44% (consult **Figure 14.5** on p. 581).

This estimate strikes most people as surprisingly high. Why is this so? One reason is that when people think about psychological disorders they tend to think of severe disorders, such as bipolar disorder or schizophrenia, which are relatively infrequent, rather than "run of the mill" disturbances, such as anxiety and depressive disorders, which are much more common. When it comes to mental illness, people tend to think of patients in straightjackets or of obviously disturbed homeless people who do not reflect the broad and diverse population of people who suffer from psychological disorders. In other words, their *prototypes* or "best examples" of mental illness consist of severe disorders that are infrequent, so they underestimate the prevalence of mental disorders. This distortion illustrates the influence of the *representativeness heuristic,* **which is basing the estimated probability of an event on how similar it is to the typical prototype of that event** (see Chapter 8).

Do you still find it hard to believe that the overall prevalence of psychological disorders is about 44%? Another reason this number seems surprisingly high is that many people do not understand that the probability of having *at least one* disorder is much higher than the probability of having the most prevalent disorder by itself. For example, the probability of having a substance use disorder, the single most common type of disorder, is approximately 24%, but the probability of having a substance use disorder *or* an anxiety disorder *or* a mood disorder *or* a schizophrenic disorder jumps to 44%. These "or" relationships represent *cumulative probabilities.* Yet another consideration that makes the prevalence figures seem high is that many people confuse different types of *prevalence rates.* The 44% estimate is for *lifetime prevalence,* which means it is the probability of having *any* disorder *at least once* at any time in one's lifetime. The lifetime prevalence rate is another example of "or" relationships. It is a value that takes into account the probability of having a psychological disorder in childhood *or* adolescence *or* adulthood *or* old age. *Point prevalence rates,* which estimate the percentage of people manifesting various disorders *at a particular point in time,* are much lower

Highly publicized insanity trials, such as that of John Hinckley, Jr., who tried to assassinate President Reagan, lead the public to greatly overestimate how often the insanity defense is used, illustrating the impact of the availability heuristic.

because many psychological disorders last only a few months to a few years.

What about "and" relationships—that is, relationships in which we want to know the probability of someone having condition A *and* condition B? For example, given the lifetime prevalence estimates (from **Figure 14.5**) for each category of disorder, which are shown in the parentheses, what is the probability of someone having a substance use disorder (24% prevalence) *and* an anxiety disorder (19%) *and* a mood disorder (15%) *and* a schizophrenic disorder (1%) during his or her lifetime? Such "and" relationships represent *conjunctive probabilities.* Stop and think: what must be true about the probability of having all four types of disorders? Will this probability be less than 24%, between 24% and 44%, or over 44%? You may be surprised to learn that this figure is probably well under 1%. You can't have all four disorders unless you have the least frequent disorder (schizophrenia), which has a prevalence of 1%, so the answer *must* be 1% or less. Moreover, of all of the people with schizophrenia, only a tiny subset of them are likely to have all three of the other disorders, so the answer is probably well under 1% (see **Figure 14.26**). If this type of question strikes you as contrived, think again. Epidemiologists have devoted an enormous amount of research to the estimation of *comorbidity*—**the coexistence of two or more disorders**—because it greatly complicates treatment issues.

These are two examples of using statistical probabilities as a critical thinking tool. Let's apply this type of thinking to another problem dealing with physical health. Here is a problem used in a study by Tversky and Kahneman (1983, p. 308) that many physicians got wrong:

A health survey was conducted in a sample of adult males in British Columbia, of all ages and occupations. Please give your best estimate of the following values:

What percentage of the men surveyed have had one or more heart attacks? _____

© Trippett/Sipa Press

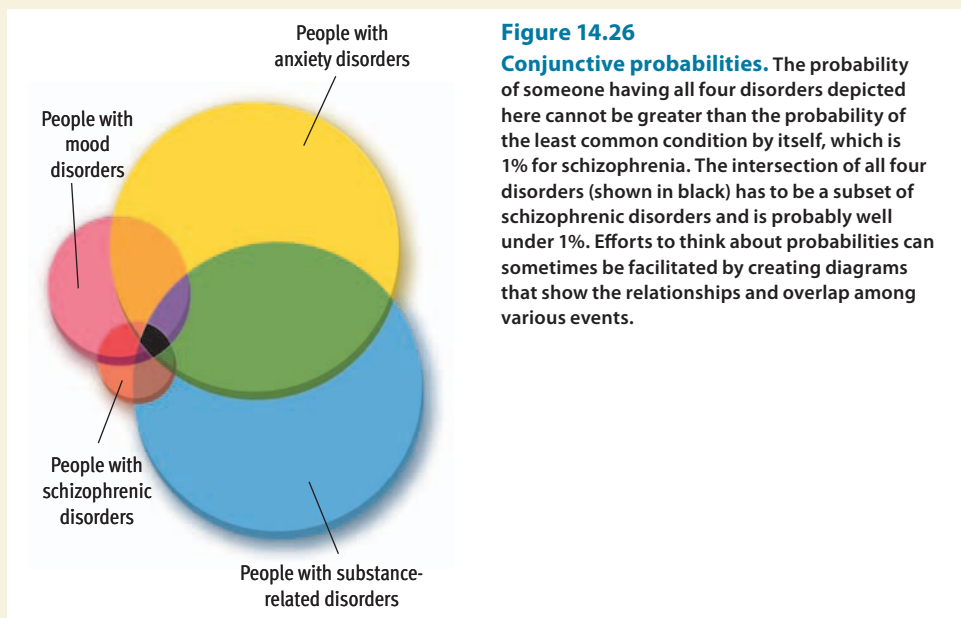
People with anxiety disorders

People with mood disorders

People with schizophrenic disorders

People with substance-related disorders

Figure 14.26

Conjunctive probabilities. The probability of someone having all four disorders depicted here cannot be greater than the probability of the least common condition by itself, which is 1% for schizophrenia. The intersection of all four disorders (shown in black) has to be a subset of schizophrenic disorders and is probably well under 1%. Efforts to think about probabilities can sometimes be facilitated by creating diagrams that show the relationships and overlap among various events.


What percentage of the men surveyed both are over 55 years old and have had one or more heart attacks? _____

Fill in the blanks above with your best guesses. Of course, you probably have only a very general idea about the prevalence of heart attacks, but go ahead and fill in the blanks anyway.

The actual values are not as important in this example as the relative values are. Over 65% of the physicians who participated in the experiment by Tversky and Kahneman gave a higher percentage value for the second question than for the first. What is wrong with their answers? The second question is asking about the conjunctive probability of two events. Hope-

fully, you see why this figure *must* be less than the probability of either one of these events occurring alone. Of all of the men in the survey who had had a heart attack, only some of them are also over 55, so the second number must be smaller than the first. As we saw in Chapter 8, this common error in thinking is called the *conjunction fallacy*. **The *conjunction fallacy* occurs when people estimate that the odds of two uncertain events happening together are greater than the odds of either event happening alone.**

Why did so many physicians get this problem wrong? They were vulnerable to the conjunction fallacy because they were influenced by the *representativeness heuristic,* or the power of prototypes. When phy-

sicians think "heart attack," they tend to envision a man over the age of 55. Hence, the second scenario fit so well with their prototype of a heart attack victim, they carelessly overestimated its probability.

Let's consider some additional examples of erroneous reasoning about probabilities involving how people think about psychological disorders. Toward the beginning of the chapter, we discussed the fact that many people tend to stereotypically assume that mentally ill people are likely to be violent. Near the end of the chapter, we noted that people tend to wildly overestimate (37-fold in one study) how often the insanity defense is used in criminal trials. These examples reflect the influence of the ***availability heuristic,* which is basing the estimated probability of an event on the ease with which relevant instances come to mind.** Because of the availability heuristic, people tend to overestimate the probability of dramatic events that receive heavy media coverage, even when these events are rare, because examples of the events are easy to retrieve from memory. Violent acts by former psychiatric patients tend to get lots of attention in the press. And because of the *hindsight bias,* journalists tend to question why authorities couldn't foresee and prevent the violence (see the Critical Thinking Application for Chapter 12), so the mental illness angle tends to be emphasized. In a similar vein, press coverage is usually intense when a defendant in a murder trial mounts an insanity defense.

In sum, the various types of statistics that come up in thinking about psychological disorders demonstrate that we are constantly working with probabilities, even though we may not realize it. Critical thinking requires a good understanding of the laws of probability because there are very few certainties in life.

Table 14.3 Critical Thinking Skills Discussed in This Application

Skill	Description
Understanding the limitations of the representativeness heuristic	The critical thinker understands that focusing on prototypes can lead to inaccurate probability estimates.
Understanding cumulative probabilities	The critical thinker understands that the probability of at least one of several events occurring is additive, and increases with time and the number of events.
Understanding conjunctive probabilities	The critical thinker appreciates that the probability of two uncertain events happening together is less than the probability of either event happening alone.
Understanding the limitations of the availability heuristic	The critical thinker understands that the ease with which examples come to mind may not be an accurate guide to the probability of an event.

REVIEW of Key Points

14.29 Probability estimates can be distorted by the representativeness heuristic and the availability heuristic. Cumulative probabilities are additive, whereas conjunctive probabilities are always less than the likelihood of any one of the events happening alone.

Key Ideas

Abnormal Behavior: Myths, Realities, and Controversies

❚ The medical model assumes that it is useful to view abnormal behavior as a disease. This view has been criticized on the grounds that it turns ethical questions about deviance into medical questions.

❚ Three criteria are used in deciding whether people suffer from psychological disorders: deviance, personal distress, and maladaptive behavior. People with psychological disorders are not particularly bizarre or dangerous, and even the most severe disorders are potentially curable.

❚ DSM-IV is the official psychodiagnostic classification system in the United States. This system asks for information about patients on five axes, or dimensions. Psychological disorders are more common than widely believed and the socioeconomic costs of mental illness are enormous.

Anxiety Disorders

❚ The anxiety disorders include generalized anxiety disorder, phobic disorder, panic disorder, obsessive-compulsive disorder, and posttraumatic stress disorder. Heredity, oversensitivity to the physiological symptoms of anxiety, and abnormalities in GABA or serotonin activity may contribute to these disorders.

❚ Many anxiety responses, especially phobias, may be caused by classical conditioning and then maintained by operant conditioning. Cognitive theorists hold that a tendency to overinterpret harmless situations as threatening may make some people vulnerable to anxiety disorders. Stress may also trigger anxiety disorders.

Somatoform Disorders

❚ Somatoform disorders include somatization disorder, conversion disorder, and hypochondriasis. These disorders often emerge in people with histrionic personalities and in people who focus excess attention on their internal physiological processes.

Dissociative Disorders

❚ Dissociative disorders include dissociative amnesia and fugue and dissociative identity disorder (DID). These disorders are uncommon and their causes are not well understood. Dissociative identity disorder is a controversial diagnosis.

Mood Disorders

❚ The principal mood disorders are major depressive disorder and bipolar disorder. Mood disorders are episodic. Depression is more common in females than males. Mood disorders are associated with dramatic elevations in suicide rates.

❚ Evidence indicates that people vary in their genetic vulnerability to mood disorders. These disorders are accompanied by changes in neurochemical activity in the brain. Depression is associated with reduced hippocampal volume and suppressed neurogenesis. Cognitive models posit that negative thinking contributes to depression. Depression is often rooted in interpersonal inadequacies and stress.

Schizophrenic Disorders

❚ Schizophrenic disorders are characterized by deterioration of adaptive behavior, delusions, hallucinations, and disturbed mood. Recognized subtypes are paranoid, catatonic, disorganized, and undifferentiated schizophrenia. Research has linked schizophrenia to genetic vulnerability, changes in neurotransmitter activity, and structural abnormalities in the brain.

❚ The neurodevelopmental hypothesis asserts that schizophrenia is attributable to disruptions in the normal maturational processes of the brain before or at birth that are caused by prenatal or obstetrical insults to the brain. Precipitating stress and high expressed emotion in families may also modulate the course of schizophrenia.

Personality Disorders

❚ Ten personality disorders, grouped into three clusters, are allocated to Axis II in the DSM. The antisocial personality disorder involves manipulative, impulsive, exploitive, aggressive behavior. Research on the etiology of this disorder has implicated genetic vulnerability, autonomic reactivity, inadequate socialization, and observational learning.

Psychological Disorders and the Law

❚ Insanity is a legal concept applied to people who cannot be held responsible for their actions because of mental illness. When people appear to be dangerous to themselves or others, courts may rule that they are subject to involuntary commitment in a hospital.

Culture and Pathology

❚ The principal categories of psychological disturbance are identifiable in all cultures, but milder disorders may go unrecognized in some societies. The symptoms associated with specific disorders are largely the same across different cultures, but some variability is seen.

Reflecting on the Chapter's Themes

❚ This chapter highlighted four of our unifying themes, showing that behavior is governed by multiple causes, that heredity and environment jointly influence mental disorders, that psychology evolves in a sociohistorical context, and that pathology is characterized by both cultural variance and invariance.

PERSONAL APPLICATION Understanding Eating Disorders

❚ The principal eating disorders are anorexia nervosa and bulimia nervosa. Binge-eating disorder has been proposed as a third diagnosis. Eating disorders appear to be largely a product of modern, affluent, Westernized culture. Females account for 90%–95% of eating disorders.

❚ There appears to be a genetic vulnerability to eating disorders. Cultural pressures on young women to be thin clearly help foster eating disorders. Unhealthful family dynamics and disturbed thinking can also contribute.

CRITICAL THINKING APPLICATION Working with Probabilities in Thinking About Mental Illness

❚ Probability estimates can be distorted by the representativeness heuristic and the availability heuristic. Cumulative probabilities are additive, whereas conjunctive probabilities are always less than the likelihood of any one of the events happening alone.

Key People

Nancy Andreasen (p. 600)
Susan Nolen-Hoeksema (pp. 592, 595)
David Rosenhan (pp. 578–579)
Martin Seligman (pp. 585, 595)
Thomas Szasz (pp. 576–577)

1. According to Thomas Szasz, abnormal behavior usually involves:
   A. behavior that is statistically unusual.
   B. behavior that deviates from social norms.
   C. a disease of the mind.
   D. biological imbalance.

2. Although Sue is plagued by a high level of dread, worry, and anxiety, she still manages to meet her daily responsibilities. Sue's behavior:
   A. should not be considered abnormal, since her adaptive functioning is not impaired.
   B. should not be considered abnormal, since everyone sometimes experiences worry and anxiety.
   C. can still be considered abnormal, since she feels great personal distress.
   D. involves both a and b.

3. The fact that people acquire phobias of ancient sources of threat (such as snakes) much more readily than modern sources of threat (such as electrical outlets) can best be explained by:
   A. classical conditioning.
   B. operant conditioning.
   C. observational learning.
   D. preparedness or an evolved module for fear learning.

4. Which of the following statements about dissociative identity disorder is true?
   A. The original personality is always aware of the alternate personalities.
   B. The alternate personalities are usually unaware of the original personality.
   C. The personalities are typically all quite similar to one another.
   D. Starting in the 1970s, a dramatic increase occurred in the diagnosis of dissociative identity disorder.

5. People with unipolar disorders experience _____; people with bipolar disorders are vulnerable to _____.
   A. alternating periods of depression and mania; mania only
   B. depression only; alternating periods of depression and mania
   C. mania only; alternating periods of depression and mania
   D. alternating periods of depression and mania; depression and mania simultaneously

6. A concordance rate indicates:
   A. the percentage of relatives who exhibit the same disorder.
   B. the percentage of people with a given disorder who are currently receiving treatment.
   C. the prevalence of a given disorder in the general population.
   D. the rate of cure for a given disorder.

7. People who consistently exhibit _____ thinking are more vulnerable to depression than others.
   A. overly optimistic   C. delusional
   B. negative, pessimistic D. dysthymic

8. Mary believes that while she sleeps at night, space creatures are attacking her and invading her uterus, where they will multiply until they are ready to take over the world. Mary would most likely be diagnosed as _____ schizophrenic.
   A. paranoid   C. disorganized
   B. catatonic   D. undifferentiated

9. As an alternative to the current classification scheme, it has been proposed that schizophrenic disorders be divided into just two categories based on:
   A. whether the prognosis is favorable or unfavorable.
   B. whether the disorder is mild or severe.
   C. the predominance of thought disturbances.
   D. the predominance of negative versus positive symptoms.

10. Most of the drugs that are useful in the treatment of schizophrenia are known to dampen _____ activity in the brain, suggesting that increases in the activity of this neurotransmitter may contribute to the development of the disorder.
    A. norepinephrine   C. acetylcholine
    B. serotonin   D. dopamine

11. The main problem with the current classification scheme for personality disorders is that:
    A. it falsely implies that nearly everyone has at least one personality disorder.
    B. the criteria for diagnosis are so detailed and specific that even extremely disturbed people fail to meet them.
    C. the categories often overlap, making diagnosis unreliable.
    D. it contains too few categories to be useful.

12. The diagnosis of antisocial personality disorder would apply to an individual who:
    A. withdraws from social interaction due to an intense fear of rejection.
    B. withdraws from social interaction due to a lack of interest.
    C. is emotionally cold and suspicious of everyone.
    D. is callous, impulsive, and manipulative.

13. Involuntary commitment to a psychiatric facility:
    A. can occur only after a mentally ill individual has been convicted of a violent crime.
    B. usually occurs because people appear to be a danger to themselves or others.
    C. no longer occurs under modern civil law.
    D. will be a lifelong commitment, even if the individual is no longer mentally ill.

14. Those who embrace a relativistic view of psychological disorders would agree that:
    A. the criteria of mental illness vary considerably across cultures.
    B. there are universal standards of normality and abnormality.
    C. Western diagnostic concepts have validity and utility in other cultural contexts.
    D. both b and c are true.

15. About _____ of patients with eating disorders are female.
    A. 40%   C. 75%
    B. 50%–60%   D. 90%–95%

TREATMENT OF PSYCHOLOGICAL DISORDERS

© RRichard T. Nowitz/National Geographic/Getty Images

What do you picture when you hear the term *psychotherapy?* Unless you've had some personal exposure to therapy, your image of it has likely been shaped by depictions you've seen on television or in the movies. A good example is the 1999 film *Analyze This,* a comedy starring Billy Crystal as psychiatrist Ben Sobol and Robert De Niro as Paul Vitti, a mob boss who is suffering from "panic attacks." Complications ensue when Vitti—a man no one says "no" to—demands that Dr. Sobol cure him of his problem before his rivals in crime turn his "weakness" against him.

With his glasses and beard, Billy Crystal's Dr. Sobol resembles many people's picture of a therapist. Like many movie therapists, Dr. Sobol practices "talk therapy." He listens attentively as his patients talk about what is troubling them. Occasionally he offers comments that reflect their thoughts and feelings back to them or that offer some illuminating insight into their problems. We can get a feeling for his approach from a funny scene in which the uneducated Vitti turns Dr. Sobol's techniques on him:

Vitti: Hey, let's see how you like it. Let's talk about your father.

Dr. Sobol: Let's not.
Vitti: What kind of work does your father do?
Dr. Sobol: It's not important.
Vitti: You paused.

The popular film Analyze This derived much of its humor from common misconceptions about the process of psychotherapy.

Warner Bros./Shooting Star

Dr. Sobol: I did not.

Vitti: You just paused. That means you had a feeling, like a thought. . . .

Dr. Sobol: You know, we're running out of time. Let's not waste it talking about my problems.

Vitti: Your father's a problem?

Dr. Sobol: No!

Vitti: That's what you just said.

Dr. Sobol: I did not!

Vitti: Now you're upset.

Dr. Sobol (getting upset): I am not upset!

Vitti: Yes you are.

Dr. Sobol: Will you stop it!

Vitti: You know what, I'm getting good at this.

As in this scene, the film derives much of its humor from popular conceptions—and misconceptions—about therapy. The technique that Vitti makes fun of does resemble one type of therapeutic process. Like Vitti, many people do associate needing therapy with a shameful weakness. Further, therapy is often of considerable benefit in assisting people to make significant changes in their lives— even if those changes are not as dramatic as Vitti's giving up his life of crime at the end of the movie. On the other hand, the film's comic exaggerations also highlight some misconceptions about therapy, including the following:

• Vitti is driven to see a "shrink" because he feels like he's "falling apart." In fact, therapists help people with all kinds of problems. People need not have severe symptoms of mental illness to benefit from therapy.

• Dr. Sobol is a psychiatrist, but most therapists are not. And although Dr. Sobol quotes Freud and the film's plot turns on interpreting a dream (in this case, it's the psychiatrist's dream!), many therapists make little or no use of Freudian techniques.

• Dr. Sobol relies on "talk therapy" to produce insights that will help his patients overcome their troubles. In reality, this approach is only one of the many techniques used by therapists.

• Dr. Sobol "cures" Vitti by getting him to acknowledge a traumatic event in his childhood (the death of his father) that is at the root of his problems. But only rarely does therapy produce a single dramatic insight that results in wholesale change for the client.

In this chapter, we'll take a down-to-earth look at *psychotherapy,* using the term in its broadest sense, to refer to all the diverse approaches used in the treatment of mental disorders and psychological problems. We'll start by discussing some general questions about the provision of treatment. After considering these issues, we'll examine the goals, techniques, and effectiveness of some of the more widely used approaches to therapy and discuss recent trends and issues in treatment. In the Personal Application, we'll look at practical questions related to finding and choosing a therapist and getting the most out of therapy. And in the Critical Thinking Application we'll address problems involved in determining whether therapy actually helps.

The Elements of the Treatment Process

Sigmund Freud is widely credited with launching modern psychotherapy. Ironically, the landmark case that inspired Freud was actually treated by one of his colleagues, Josef Breuer. Around 1880, Breuer began to treat a young woman referred to as Anna O (which was a pseudonym—her real name was Bertha Pappenheim). Anna exhibited a variety of physical maladies, including headaches, coughing, and a loss of feeling and movement in her right arm. Much to his surprise, Breuer discovered that Anna's physical symptoms cleared up when he encouraged her to talk about emotionally charged experiences from her past.

When Breuer and Freud discussed the case, they speculated that talking things through had enabled Anna to drain off bottled-up emotions that had caused her symptoms. Breuer found the intense emotional exchange in this treatment not to his liking, so he didn't follow through on his discovery. However, Freud applied Breuer's insight to other patients, and his successes led him to develop a systematic treatment procedure, which he called *psychoanalysis.* Anna O called her treatment "the talking cure." However, as you'll see, psychotherapy isn't always curative, and many modern treatments place little emphasis on talking.

Freud's breakthrough ushered in a century of progress for psychotherapy. Psychoanalysis spawned many offspring as Freud's followers developed their own systems of treatment. Since then, approaches

to treatment have steadily grown more numerous, more diverse, and more effective. Today, people can choose from a bewildering array of therapies.

Treatments: How Many Types Are There?

In their efforts to help people, psychotherapists use many treatment methods. These methods include discussion, advice, emotional support, persuasion, conditioning procedures, relaxation training, role playing, drug therapy, biofeedback, and group therapy. No one knows exactly how many distinct types of psychotherapy there are. One expert (Kazdin, 1994) estimates that there may be over 400 approaches to treatment. Fortunately, we can impose some order on this chaos. As varied as therapists' procedures are, approaches to treatment can be classified into three major categories:

1. *Insight therapies.* Insight therapy is "talk therapy" in the tradition of Freud's psychoanalysis. In insight therapies, clients engage in complex verbal interactions with their therapists. The goal in these discussions is to pursue increased insight regarding the nature of the client's difficulties and to sort through possible solutions. Insight therapy can be conducted with an individual or with a group. Broadly speaking, family therapy and marital therapy fall into this category.

2. *Behavior therapies.* Behavior therapies are based on the principles of learning, which were introduced in Chapter 6. Instead of emphasizing personal insights, behavior therapists make direct efforts to alter problematic responses (phobias, for instance) and maladaptive habits (drug use, for instance). Behavior therapists work on changing clients' overt behaviors. They use different procedures for different kinds of problems.

3. *Biomedical therapies.* Biomedical approaches to therapy involve interventions into a person's biological functioning. The most widely used procedures are drug therapy and electroconvulsive (shock) therapy. As the term bio*medical* suggests, these treatments have traditionally been provided only by physicians with a medical degree (usually psychiatrists). This situation is changing, however, as psychologists have been campaigning for prescription privileges (Norfleet, 2002; Welsh, 2003). To date psychologists have obtained prescription authority in two states (New Mexico and Louisiana), and they have made legislative progress toward this goal in many other states (Long, 2005). Although some psychologists have argued against pursuing the right to prescribe medication (Heiby, 2002; Robiner et al.,

2003), the movement is gathering momentum and seems likely to prevail.

Clients: Who Seeks Therapy?

In the therapeutic triad (therapists, treatments, clients), the greatest diversity is seen among the clients. According to the 1999 Surgeon General's report on mental health (U.S. Department of Health and Human Services, 1999) about 15% of the U.S. population use mental health services in a given year. These people bring to therapy the full range of human problems: anxiety, depression, unsatisfactory interpersonal relations, troublesome habits, poor self-control, low self-esteem, marital conflicts, self-doubt, a sense of emptiness, and feelings of personal stagnation. The two most common presenting problems are excessive anxiety and depression (Narrow et al., 1993).

Interestingly, people often delay for many years before finally seeking treatment for their psychological problems (Kessler, Olfson, & Berglund, 1998). One recent large-scale study (Wang, Berglund et al., 2005) found that the median delay in seeking treatment was 6 years for bipolar disorder and for drug dependence, 8 years for depression, 9 years for generalized anxiety disorder, and 10 years for panic disorder! Figure 15.1 summarizes data from the same study on the percentage of people with various disorders who seek treatment within the first year after the onset of the disorder. As you can see, the figures are surprisingly low for most disorders.

A client in treatment does *not* necessarily have an identifiable psychological disorder. Some people seek professional help for everyday problems (career decisions, for instance) or vague feelings of discontent

The case of Anna O, whose real name was Bertha Pappenheim, provided the inspiration for Sigmund Freud's invention of psychoanalysis.

Figure 15.1

Treatment seeking for various disorders. In a study of the extent to which people seek treatment for psychological disorders, Wang et al. (2005) found that only a minority of people promptly pursue treatment for their disorder. The data summarized here show the percentage of people who obtain professional treatment within the first year after the onset of various disorders. The percentages vary depending on the disorder, but all the figures are surprisingly low.

Type of disorder / Portion who obtained treatment in first year after onset (%)
(Strupp, 1996). One surprising finding in recent research has been that only about half of the people who use mental health services in a given year meet the criteria for a full-fledged mental disorder (Kessler et al., 2005b).

People vary considerably in their willingness to seek psychotherapy. One study found that even among people who perceive a need for professional assistance, only 59% actually seek professional help (Mojtabai, Olfson, & Mechanic, 2002). As you can see in **Figure 15.2**, women are more likely than men to receive therapy. Treatment is also more likely when people have medical insurance and when they have more education (Olfson et al., 2002; Wang,

Lane et al., 2005). *Unfortunately, it appears that many people who need therapy don't receive it* (Kessler et al., 2005b). As **Figure 15.3** shows, only a portion of the people who need treatment get it. People who could benefit from therapy do not seek it for a variety of reasons. Lack of health insurance and cost concerns appear to be major barriers to obtaining needed care for many people. According to the Surgeon General's report, the biggest roadblock is the "stigma surrounding the receipt of mental health treatment." Unfortunately, many people equate seeking therapy with admitting personal weakness.

Therapists: Who Provides Professional Treatment?

People troubled by personal problems often solicit help from their friends, relatives, and clergy. These sources of assistance may provide excellent advice, but their counsel does not qualify as therapy. Therapy refers to *professional* treatment by someone with special training. However, a common source of confusion about psychotherapy is the variety of "helping professions" available to offer assistance (Murstein & Fontaine, 1993). Psychology and psychiatry are the principal professions involved in the provision of psychotherapy. However, therapy is increasingly provided by clinical social workers, psychiatric nurses, counselors, and marriage and family therapists. Let's look at the various mental health professions.

Psychologists

Two types of psychologists may provide therapy. *Clinical psychologists* and *counseling psychologists* specialize in the diagnosis and treatment of psychological disorders and everyday behavioral problems. Clinical psychologists' training emphasizes the treatment of full-fledged disorders. In contrast, counseling psychologists' training is slanted toward the treatment of everyday adjustment problems. In practice, however, quite a bit of overlap occurs between clinical and counseling psychologists in training, skills, and the clientele that they serve.

Both types of psychologists must earn a doctoral degree (Ph.D., Psy.D., or Ed.D.). A doctorate in psychology requires about five to seven years of training beyond a bachelor's degree. The process of gaining admission to a Ph.D. program in clinical psychology is highly competitive (about as difficult as getting into medical school). Psychologists receive most of their training in universities or independent professional schools. They then serve a one-year internship in a clinical setting, such as a hospital, usually followed by one or two years of postdoctoral fellowship training.

Figure 15.2

Therapy utilization rates. Olfson and colleagues (2002) gathered data on the use of non-hospital outpatient mental health services in the United States in relation to various demographic variables. In regard to marital status, utilization rates are particularly high among those who are divorced or separated. The use of therapy is greater among those who have more education; in terms of age, utilization peaks in the 35–44 age bracket. Females are more likely to pursue therapy than males are, but utilization rates are extremely low among ethnic minorities.
In providing therapy, psychologists use either insight or behavioral approaches. In comparison to psychiatrists, they are more likely to use behavioral techniques and less likely to use psychoanalytic methods. Clinical and counseling psychologists do psychological testing as well as psychotherapy, and many also conduct research.

Psychiatrists

Psychiatrists **are physicians who specialize in the diagnosis and treatment of psychological disorders.** Many psychiatrists also treat everyday behavioral problems. However, in comparison to psychologists, psychiatrists devote more time to relatively severe disorders (schizophrenia, mood disorders) and less time to everyday marital, family, job, and school problems.

Psychiatrists have an M.D. degree. Their graduate training requires four years of coursework in medical school and a four-year apprenticeship in a residency at a hospital. Their psychotherapy training occurs during their residency, since the required coursework in medical school is essentially the same for everyone, whether they are going into surgery, pediatrics, or psychiatry. In their provision of therapy, psychiatrists increasingly emphasize drug therapies (Olfson et al., 2002). In comparison to psychologists, psychiatrists are more likely to use psychoanalysis and less likely to use group therapies or behavior therapies. That said, contemporary psychiatrists primarily depend on medication as their principal mode of treatment.

Other Mental Health Professionals

Several other mental health professions also provide psychotherapy services, and some of these professions are growing rapidly. In hospitals and other institutions, *clinical social workers* and *psychiatric nurses* often work as part of a treatment team with a psychologist or psychiatrist. Psychiatric nurses, who may have a bachelor's or master's degree in their field, play a large role in hospital inpatient treatment. Clinical social workers generally have a master's degree and typically work with patients and their families to ease the patient's integration back into the community. Although social workers and psychiatric nurses have traditionally worked in institutional settings, they increasingly provide a wide range of therapeutic services as independent practitioners.

Many kinds of *counselors* also provide therapeutic services. Counselors are usually found working in schools, colleges, and assorted human service agencies (youth centers, geriatric centers, family planning centers, and so forth). Counselors typically have a master's degree. They often specialize
Figure 15.3

Psychological disorders and professional treatment. Not everyone who has a psychological disorder receives professional treatment, and not everyone who seeks treatment has a clear disorder. This graph, from the Surgeon General's report on mental health, shows that 15% of the U.S. adult population receive mental health treatment each year. Almost half of these people (7%) do not receive a psychiatric diagnosis, although some of them probably have milder disorders that are not assessed in epidemiological research. This graph also shows that over two-thirds of the people who *do* have disorders do *not* receive professional treatment. (Data from *Mental Health: A Report of the Surgeon General,* U.S. Public Health Service, 1999)

in particular types of problems, such as vocational counseling, marital counseling, rehabilitation counseling, and drug counseling.

Although there are clear differences among the helping professions in education and training, their roles in the treatment process overlap considerably. In this chapter, we will refer to psychologists or psychiatrists as needed, but otherwise we'll use the terms *clinician, therapist,* and *provider* to refer to mental health professionals of all kinds, regardless of their professional degree.

Now that we have discussed the basic elements in psychotherapy, we can examine specific approaches to treatment in terms of their goals, procedures, and effectiveness. We'll begin with some representative insight therapies.

Online Dictionary of Mental Health

This thematically arranged "dictionary" at the University of Sheffield (UK) Medical School comprises diverse links related to many forms of psychotherapy, the treatment of psychological disorders, and general issues of mental health.

REVIEW of Key Points

15.1 Approaches to treatment are diverse, but they can be grouped into three categories: insight therapies, behavior therapies, and biomedical therapies. Clients bring a wide variety of problems to therapy and do not necessarily have a disorder. People vary in their willingness to seek treatment. Many people delay seeking treatment, and many who need therapy do not receive it.

15.2 Therapists come from a variety of professional backgrounds. Clinical and counseling psychologists, psychiatrists, clinical social workers, psychiatric nurses, and counselors are the principal providers of therapeutic services. Each of these professions shows different preferences for approaches to treatment. Psychologists typically practice insight or behavior therapy. Psychiatrists rely more heavily on drug therapies.

There are many schools of thought about how to do insight therapy. Therapists with various theoretical orientations use different methods to pursue different kinds of insights. However, what these varied approaches have in common is that *insight therapies involve verbal interactions intended to enhance clients' self-knowledge and thus promote healthful changes in personality and behavior.*

Although there may be hundreds of insight therapies, the leading eight or ten approaches appear to account for the lion's share of treatment. In this section, we'll delve into psychoanalysis, related psychodynamic approaches, client-centered therapy, and new approaches fostered by the positive psychology movement. We'll also discuss how insight therapy can be done with groups as well as individuals.

Psychoanalysis 11d

After the case of Anna O, Sigmund Freud worked as a psychotherapist for almost 50 years in Vienna. Through a painstaking process of trial and error, he developed innovative techniques for the treatment of psychological disorders and distress. His system of *psychoanalysis* came to dominate psychiatry for many decades. Although this dominance has eroded in recent years, a diverse collection of psychoanalytic approaches to therapy continue to evolve and to remain influential today (Gabbard, 2005; McWilliams & Weinberger, 2003; Ursano & Silberman, 2003).

Psychoanalysis **is an insight therapy that emphasizes the recovery of unconscious conflicts, motives, and defenses through techniques such as free association and transference.** To appreciate the logic of psychoanalysis, we have to look at Freud's thinking about the roots of mental disorders. Freud mostly treated anxiety-dominated disturbances, such as phobic, panic, obsessive-compulsive, and conversion disorders, which were then called *neuroses.*

Freud believed that neurotic problems are caused by unconscious conflicts left over from early childhood. As explained in Chapter 12, he thought that these inner conflicts involve battles among the id, ego, and superego, usually over sexual and aggressive impulses. He theorized that people depend on defense mechanisms to avoid confronting these conflicts, which remain hidden in the depths of the unconscious (see **Figure 15.4**). However, he noted that defensive maneuvers often lead to self-defeating be-

havior. Furthermore, he asserted that defenses tend to be only partially successful in alleviating anxiety, guilt, and other distressing emotions. With this model in mind, let's take a look at the therapeutic procedures used in psychoanalysis.

Probing the Unconscious 11d

Given Freud's assumptions, we can see that the logic of psychoanalysis is quite simple. The analyst attempts to probe the murky depths of the unconscious to discover the unresolved conflicts causing the client's neurotic behavior. In a sense, the analyst functions as a "psychological detective." In this effort to explore the unconscious, the therapist relies on two techniques: free association and dream analysis.

In *free association* **clients spontaneously express their thoughts and feelings exactly as they occur, with as little censorship as possible.** In free associating, clients expound on anything that comes to mind, regardless of how trivial, silly, or embarrassing it might be. Gradually, most clients begin to let everything pour out without conscious censorship. The analyst studies these free associations for clues about what is going on in the client's unconscious.

In *dream analysis* **the therapist interprets the symbolic meaning of the client's dreams.** Freud saw dreams as the "royal road to the unconscious," the most direct means of access to patients' innermost conflicts, wishes, and impulses. Clients are encouraged and trained to remember their dreams, which they describe in therapy. The therapist then analyzes the symbolism in these dreams to interpret their meaning.

To better illustrate these matters, let's look at an actual case treated through psychoanalysis (adapted from Greenson, 1967, pp. 40–41). Mr. N was troubled by an unsatisfactory marriage. He claimed to love his wife, but he preferred sexual relations with prostitutes. Mr. N reported that his parents also endured lifelong marital difficulties. His childhood conflicts about their relationship appeared to be related to his problems. Both dream analysis and free association can be seen in the following description of a session in Mr. N's treatment:

Mr. N reported a fragment of a dream. All that he could remember is that he was waiting for a red traffic light to change when he felt that someone had bumped into

Sigmund Freud

"The news that reaches your consciousness is incomplete and often not to be relied on."

National Library of Medicine

him from behind. . . . The associations led to Mr. N's love of cars, especially sports cars. He loved the sensation, in particular, of whizzing by those fat, old expensive cars. . . .

His father always hinted that he had been a great athlete, but he never substantiated it. . . . Mr. N doubted whether his father could really perform. His father would flirt with a waitress in a cafe or make sexual remarks about women passing by, but he seemed to be showing off. If he were really sexual, he wouldn't resort to that.

As is characteristic of free association, Mr. N's train of thought meandered about with little direction. Nonetheless, clues about his unconscious conflicts are apparent. What did Mr. N's therapist extract from this session? The therapist saw sexual overtones in the dream fragment, where Mr. N was bumped from behind. The therapist also inferred that Mr. N had a competitive orientation toward his father, based on the free association about whizzing by fat, old expensive cars. As you can see, analysts must *interpret* their clients' dreams and free associations. This is a critical process throughout psychoanalysis.

Interpretation   11d

Interpretation **refers to the therapist's attempts to explain the inner significance of the client's thoughts, feelings, memories, and behaviors.** Contrary to popular belief, analysts do not interpret everything, and they generally don't try to dazzle clients with startling revelations. Instead, analysts move forward inch by inch, offering interpretations that should be just out of the client's own reach (Samberg & Marcus, 2005). Mr. N's therapist eventually offered the following interpretations to his client:

I said to Mr. N near the end of the hour that I felt he was struggling with his feelings about his father's sexual life. He seemed to be saying that his father was sexually not a very potent man. . . . He also recalls that he once found a packet of condoms under his father's pillow when he was an adolescent and he thought, "My father must be going to prostitutes." I then intervened and pointed out that the condoms under his father's pillow seemed to indicate more obviously that his father used the condoms with his mother, who slept in the same bed. However, Mr. N wanted to believe his wish-fulfilling fantasy: mother doesn't want sex with father and father is not very potent. The patient was silent and the hour ended.

As you may have already guessed, the therapist concluded that Mr. N's difficulties were rooted in an Oedipal complex (see Chapter 12). The man had

| Intrapsychic conflict (between id, ego, and superego) | → | Anxiety | → | Reliance on defense mechanisms |

Figure 15.4
Freud's view of the roots of disorders. According to Freud, unconscious conflicts among the id, ego, and superego sometimes lead to anxiety. This discomfort may lead to pathological reliance on defensive behavior.

unresolved sexual feelings toward his mother and hostile feelings about his father. These unconscious conflicts, rooted in Mr. N's childhood, were distorting his intimate relations as an adult.

Resistance   11d

How would you expect Mr. N to respond to the therapist's suggestion that he was in competition with his father for the sexual attention of his mother? Obviously, most clients would have great difficulty accepting such an interpretation. Freud fully expected clients to display some resistance to therapeutic efforts. *Resistance* **refers to largely unconscious defensive maneuvers intended to hinder the progress of therapy.** Resistance is assumed to be an inevitable part of the psychoanalytic process (Samberg & Marcus, 2005). Why would clients try to resist the helping process? Because they don't want to face up to the painful, disturbing conflicts that they have buried in their unconscious. Although they have sought help, they are reluctant to confront their real problems.

Resistance can take many forms. Clients may show up late for their sessions, may merely pretend to engage in free association, or may express hostility toward their therapist. For instance, Mr. N's therapist noted that after the session just described, "The next day he [Mr. N] began by telling me that he was furious with me . . ." Analysts use a variety of strategies to deal with their clients' resistance. Often, a key consideration is the handling of transference, which we consider next.

In psychoanalysis, the therapist encourages the client to reveal thoughts, feelings, dreams, and memories, which can then be interpreted in relation to the client's current problems.

© Bruce Ayres/Stone/Getty Images

Transference

Transference **occurs when clients unconsciously start relating to their therapist in ways that mimic critical relationships in their lives.** Thus, a client might start relating to a therapist as if the therapist were an overprotective mother, a rejecting brother, or a passive spouse. In a sense, the client *transfers* conflicting feelings about important people onto the therapist. For instance, in his treatment, Mr. N transferred some of the competitive hostility he felt toward his father onto his analyst.

Psychoanalysts often encourage transference so that clients can reenact relations with crucial people in the context of therapy. These reenactments can help bring repressed feelings and conflicts to the surface, allowing the client to work through them. The therapist's handling of transference is complicated and difficult, because transference may arouse confusing, highly charged emotions in the client.

Undergoing psychoanalysis is not easy. It can be a slow, painful process of self-examination that routinely requires three to five years of hard work. It tends to be a lengthy process because patients need time to gradually work through their problems and genuinely accept unnerving revelations (Williams, 2005). Ultimately, if resistance and transference can be handled effectively, the therapist's interpretations should lead the client to profound insights. For instance, Mr. N eventually admitted, "The old boy is probably right, it does tickle me to imagine that my mother preferred me and I could beat out my father. Later, I wondered whether this had something to do with my own screwed-up sex life with my wife." According to Freud, once clients recognize the unconscious sources of conflicts, they can resolve these conflicts and discard their neurotic defenses.

Modern Psychodynamic Therapies

Though still available, classical psychoanalysis as done by Freud is not widely practiced anymore (Kay & Kay, 2003). Freud's psychoanalytic method was geared to a particular kind of clientele that he was seeing in Vienna many years ago. As his followers fanned out across Europe and America, many found it necessary to adapt psychoanalysis to different cultures, changing times, and new kinds of patients (Karasu, 2005). Thus, many variations on Freud's original approach to psychoanalysis have developed over the years. These descendants of psychoanalysis, which continue to emphasize exploration of the unconscious, are collectively known as *psychodynamic approaches* to therapy.

Some of these adaptations, such as those made by Carl Jung (1917) and Alfred Adler (1927), were sweeping revisions based on fundamental differences in

theory. Other variations, such as those devised by Melanie Klein (1948) and Heinz Kohut (1971), made substantial changes in theory while retaining certain central ideas. Still other revisions (Alexander, 1954; Stekel, 1950) simply involved efforts to modernize and streamline psychoanalytic techniques.

As a result, today we have a rich diversity of psychodynamic approaches to therapy (Magnavita, 2008). Recent reviews of these treatments suggest that interpretation, resistance, and transference continue to play key roles in therapeutic effects (Luborsky & Barrett, 2006). For example, evidence suggests that the amount of resistance manifested in psychodynamic therapy predicts the outcome of therapy. People who exhibit more resistance are less likely to experience a positive outcome and more likely to drop out of therapy (Luborsky & Barrett, 2006). Recent research also suggests that psychodynamic approaches can be helpful in the treatment of a diverse array of disorders, including panic disorder, borderline personality disorder, and substance abuse (Gibbons, Crits-Christoph, & Hearon, 2008).

Client-Centered Therapy

You may have heard of people going into therapy to "find themselves" or to "get in touch with their real feelings." These now-popular phrases emerged out of the human potential movement, which was stimulated in part by the work of Carl Rogers (1951, 1986). Using a humanistic perspective, Rogers devised *client-centered therapy* (also known as *person-centered therapy*) in the 1940s and 1950s.

Client-centered therapy **is an insight therapy that emphasizes providing a supportive emotional climate for clients, who play a major role in determining the pace and direction of their therapy.** You may wonder why the troubled, untrained client is put in charge of the pace and direction of the therapy. Rogers (1961) provides a compelling justification:

It is the client who knows what hurts, what directions to go, what problems are crucial, what experiences have been deeply buried. It began to occur to me that unless I had a need to demonstrate my own cleverness and learning, I would do better to rely upon the client for the direction of movement in the process. (pp. 11–12)

Rogers's theory about the principal causes of neurotic anxieties is quite different from the Freudian explanation. As discussed in Chapter 12, Rogers maintains that most personal distress is due to inconsistency, or "incongruence," between a person's self-concept and reality (see **Figure 15.5**). Accord-
Figure 15.5
Rogers's view of the roots of disorders. Rogers's theory posits that anxiety and self-defeating behavior are rooted in an incongruent self-concept that makes one prone to recurrent anxiety, which triggers defensive behavior, which fuels more incongruence.

ing to his theory, incongruence makes people feel threatened by realistic feedback about themselves from others. For example, if you inaccurately viewed yourself as a hard-working, dependable person, you would feel threatened by contradictory feedback from friends or co-workers. According to Rogers, anxiety about such feedback often leads to reliance on defense mechanisms, to distortions of reality, and to stifled personal growth. Excessive incongruence is thought to be rooted in clients' overdependence on others for approval and acceptance.

Given Rogers's theory, client-centered therapists stalk insights that are quite different from the repressed conflicts that psychoanalysts go after. Client-centered therapists help clients to realize that they do not have to worry constantly about pleasing others and winning acceptance. They encourage clients to respect their own feelings and values. They help people restructure their self-concept to correspond better to reality. Ultimately, they try to foster self-acceptance and personal growth.

Therapeutic Climate   11d

According to Rogers, the *process* of therapy is not as important as the emotional *climate* in which the therapy takes place. He believes that it is critical for the therapist to provide a warm, supportive, accepting climate, which creates a safe environment in which clients can confront their shortcomings without feeling threatened. The lack of threat should reduce clients' defensive tendencies and thus help them open up. To create this atmosphere of emotional support, client-centered therapists must provide three conditions:

1. *Genuineness.* The therapist must be genuine with the client, communicating honestly and spontaneously. The therapist should not be phony or defensive.

2. *Unconditional positive regard.* The therapist must also show complete, nonjudgmental acceptance of the client as a person. The therapist should provide warmth and caring for the client, with no strings attached. This does not mean that the therapist must approve of everything that the client says or does.

A therapist can disapprove of a particular behavior while continuing to value the client as a human being.

3. *Empathy.* Finally, the therapist must provide accurate empathy for the client. This means that the therapist must understand the client's world from the client's point of view. Furthermore, the therapist must be articulate enough to communicate this understanding to the client.

Rogers firmly believed that a supportive emotional climate is the critical force promoting healthy changes in therapy. More recently, however, some client-centered therapists have begun to place more emphasis on the therapeutic process (Rice & Greenberg, 1992).

Therapeutic Process   11d

In client-centered therapy, the client and therapist work together as equals. The therapist provides relatively little guidance and keeps interpretation and advice to a minimum. So, just what does the client-centered therapist do, besides creating a supportive climate? Primarily, the therapist provides feedback to help clients sort out their feelings. The therapist's key task is *clarification.* Client-centered therapists try

Carl Rogers
"To my mind, empathy is in itself a healing agent."

Client-centered therapists emphasize the importance of a supportive emotional climate in therapy. They also work to clarify, rather than interpret, the feelings expressed by their patients.

to function like a human mirror, reflecting statements back to their clients, but with enhanced clarity. They help clients become more aware of their true feelings by highlighting themes that may be obscure in the clients' rambling discourse.

By working with clients to clarify their feelings, client-centered therapists hope to gradually build toward more far-reaching insights. In particular, they try to help clients better understand their interpersonal relationships and become more comfortable with their genuine selves. Obviously, these are ambitious goals. Client-centered therapy resembles psychoanalysis in that both seek to achieve a major reconstruction of a client's personality.

Therapies Inspired by Positive Psychology

The growth of the positive psychology movement has begun to inspire new approaches to insight therapy (Duckworth, Steen, & Seligman, 2005). As noted in Chapters 1 and 10, *positive psychology uses theory and research to better understand the positive, adaptive, creative, and fulfilling aspects of human existence.* The advocates of positive psychology maintain that the field has historically focused far too heavily on pathology, weakness, and suffering (and how to heal these conditions) rather than health and resilience (Seligman, 2003; Seligman & Csikszentmihalyi, 2000). They argue for increased research on contentment, well-being, human strengths, and positive emotions.

This philosophical approach has led to new therapeutic interventions. For example, *well-being therapy,* developed by Giovanni Fava and his colleagues (Fava, 1999; Ruini & Fava, 2004), seeks to enhance clients' self-acceptance, purpose in life, autonomy, and personal growth. It has been used successfully in the treatment of mood disorders and anxiety disorders (Fava et al., 2005).

Another new approach is *positive psychotherapy,* developed by Martin Seligman and colleagues (Seligman, Rashid, & Parks, 2006). Thus far, positive psychotherapy has been used mainly in the treatment of depression. This approach attempts to get clients to recognize their strengths, appreciate their blessings, savor positive experiences, forgive those who have wronged them, and find meaning in their lives. Preliminary research suggests that positive psychotherapy can be an effective treatment for depression. For example, in one study it was compared to treatment as usual (whatever the therapist would normally do) and treatment as usual with medication. The data shown in **Figure 15.6** compare mean depres-
Figure 15.6

Positive psychotherapy for depression. In a study of the efficacy of positive psychotherapy, it was compared to treatment as usual (clinicians delivered whatever treatment they deemed appropriate) and to treatment as usual combined with antidepressant medication. At the end of 12 weeks of treatment, symptoms of depression were measured with the widely-used Hamilton Rating Scale for Depression. The mean depression scores for each group are graphed here. As you can see, the positive psychotherapy group showed less depression than the other two treatment groups, suggesting that positive psychotherapy can be an effective intervention for depression.

SOURCE: Adapted from Seligman, M. E. P., Rashid, T., & Parks, A. C. (2006). Positive psychotherapy. *American Psychologist, 61,* 774–788. (Figure 2, p. 784).

sion scores at the end of the study for participants in these three conditions (Seligman et al., 2006). As you can see, the lowest depression scores were observed in the group that received positive psychotherapy. These innovative interventions spurred by the positive psychology movement are in their infancy, but the early findings seem promising, and it will be interesting to see what the future holds.

Group Therapy

Although it dates back to the early part of the 20th century, group therapy came of age during World War II and its aftermath in the 1950s (Rosenbaum, Lakin, & Roback, 1992). During this period, the expanding demand for therapeutic services forced clinicians to use group techniques (Scheidlinger, 1993). *Group therapy* is the simultaneous psychological treatment of several clients in a group. Most major insight therapies have been adapted for use with groups. Because of economic pressures in mental health care, the use of group therapy appears likely to grow in future years (Burlingame & McClendon,

2008). Although group therapy can be conducted in a variety of ways, we will provide a general overview of the process as it usually unfolds with outpatient populations (see Alonso, Alonso, & Piper, 2003; Vinogradov, Cox, & Yalom, 2003; Wong, 2005).

Participants' Roles

A therapy group typically consists of 4–12 people, with 6–8 participants regarded as an ideal number (Vinogradov et al., 2003). The therapist usually screens the participants, excluding persons who seem likely to be disruptive. Some theorists maintain that judicious selection of participants is crucial to effective group treatment (Salvendy, 1993). There is some debate about whether it is better for the group to be homogeneous—made up of people who are similar in age, sex, and psychological problem. Practical necessities usually dictate that groups are at least somewhat diversified.

In group therapy, participants essentially function as therapists for one another (Stone, 2003). Group members describe their problems, trade viewpoints, share experiences, and discuss coping strategies. Most important, they provide acceptance and emotional support for each other. In this supportive atmosphere, group members work at peeling away the social masks that cover their insecurities. Once their problems are exposed, members work at correcting them. As members come to value one another's opinions, they work hard to display healthy changes to win the group's approval.

In group treatment, the therapist's responsibilities include selecting participants, setting goals for the group, initiating and maintaining the therapeutic process, and protecting clients from harm (Vinogradov et al., 2003). The therapist often plays a relatively subtle role in group therapy, staying in the background and focusing mainly on promoting group cohesiveness (although this strategy will vary depending on the nature of the group). The therapist models supportive behaviors for the participants and tries to promote a healthy climate. He or she always retains a special status, but the therapist and clients are usually on much more equal footing in group therapy than in individual therapy. The leader in group therapy expresses emotions, shares feelings, and copes with challenges from group members (Burlingame & McClendon, 2008).

Advantages of the Group Experience

Group therapies obviously save time and money, which can be critical in understaffed mental hospitals and other institutional settings (Vinogradov et al., 2003). Therapists in private practice usually charge less for group than individual therapy, making therapy affordable for more people. However, group therapy is *not* just a less costly substitute for individual therapy. For many types of patients and problems, group therapy can be just as effective as individual treatment (Knauss, 2005; Stone, 2003). Moreover, group therapy has unique strengths of its own. For example, in group therapy participants often come to realize that their misery is not unique. They are reassured to learn that many other people have similar or even worse problems. Another advantage is that group therapy provides an opportunity for participants to work on their social skills in a safe environment. Yet another plus is that certain types of problems and clients respond especially well to the social support that group therapy can provide.

© John Greim/Photo Researchers, Inc.

Group treatments have proven particularly helpful when members share similar problems, such as alcoholism, overeating, or having been sexually abused as a child. Many approaches to insight therapy that were originally designed for individuals—such as client-centered therapy—have been adapted for treatment of groups.

concept check 15.1

Understanding Therapists' Conceptions of Disorders

Check your understanding of the three approaches to insight therapy covered in the text by matching each approach with the appropriate explanation of the typical origins of clients' psychological disorders. The answers are in Appendix A.

Theorized causes of disorders

_____ 1. Problems rooted in inadequate attention paid to one's strengths, blessings, and positive experiences

_____ 2. Problems rooted in unconscious conflicts left over from childhood

_____ 3. Problems rooted in inaccurate self-concept and excessive concern about pleasing others

Therapy

a. Psychoanalysis

b. Client-centered therapy

c. Positive psychotherapy

Whether insight therapies are conducted on a group or an individual basis, clients usually invest considerable time, effort, and money. Are these therapies worth the investment? Let's examine the evidence on their effectiveness.

How Effective Are Insight Therapies?

Evaluating the effectiveness of any approach to treatment is a complex challenge (Hill & Lambert, 2004; Kendall, Holmbeck, & Verduin, 2004). For one thing, psychological disorders (like many physical illnesses) sometimes run their course and clear up on their own. **A *spontaneous remission* is a recovery from a disorder that occurs without formal treatment.** Thus, if a client experiences a recovery after treatment, one cannot automatically assume that the recovery was due to the treatment (see the Critical Thinking Application).

Evaluating the effectiveness of treatment is especially complicated for insight therapies (Aveline, Strauss, & Stiles, 2005). If you were to undergo insight therapy, how would you judge its efficacy? By how you felt? By looking at your behavior? By asking your therapist? By consulting your friends and family? What would you be looking for? Various schools of thought pursue entirely different goals. And clients' ratings of their progress are likely to be slanted toward a favorable evaluation because they want to justify their effort, their heartache, their expense, and their time. Even evaluations by professional therapists can be highly subjective (Luborsky et al., 1999). Moreover, people enter therapy with diverse problems of varied severity, creating huge confounds in efforts to assess the effectiveness of therapeutic interventions.

Despite these difficulties, thousands of outcome studies have been conducted to evaluate the effectiveness of insight therapy. These studies have examined a broad range of clinical problems and used diverse methods to assess therapeutic outcomes, including scores on psychological tests and ratings by family members, as well as therapists' and clients' ratings. These studies consistently indicate that insight therapy *is* superior to no treatment or to placebo treatment and that the effects of therapy are reasonably durable (Kopta et al., 1999; Lambert & Archer, 2006). And when insight therapies are compared head-to-head against drug therapies, they usually show roughly equal efficacy (Arkowitz & Lilienfeld, 2007; Pinquart, Duberstein, & Lyness, 2006). Studies generally find the greatest improvement early in treatment (the first 13–18 weekly sessions), with further gains gradually diminishing over time (Lambert, Bergin, & Garfield, 2004). Overall, about 50% of patients show a clinically meaningful recovery within about 20 sessions, and another 25% of patients achieve this goal after about 45 sessions (Lambert & Ogles, 2004; see **Figure 15.7**). Of course, these broad generalizations mask considerable variability in outcome, but the general trends are encouraging.

How Do Insight Therapies Work?

Although there is considerable evidence that insight therapy tends to produce positive effects for a sizable majority of clients, vigorous debate continues about the *mechanisms of action* underlying these positive effects (Kazdin, 2007). The advocates of various therapies tend to attribute the benefits of therapy to the particular methods and procedures used by each specific approach (Chambless & Hollon, 1998). In essence, they argue that different therapies achieve similar benefits through different processes. An alternative view espoused by many theorists is that the diverse approaches to therapy share certain *common factors* and that these common factors account for much of the improvement experienced by clients (Frank & Frank, 1991). Evidence supporting the common factors view has mounted in recent years (Ahn & Wampold, 2001; Sparks, Duncan, & Miller, 2008).

What are the common denominators that lie at the core of diverse approaches to therapy? The models proposed to answer to this question vary consid-

INSIDE WOODY ALLEN
erably, but the most widely cited common factors include (1) the development of a therapeutic alliance with a professional helper, (2) the provision of emotional support and empathic understanding by the therapist, (3) the cultivation of hope and positive expectations in the client, (4) the provision of a rationale for the client's problems and a plausible method for reducing them, and (5) the opportunity to express feelings, confront problems, gain new insights, and learn new patterns of behavior (Grencavage & Norcross, 1990; Weinberger, 1995). How important are these factors in therapy? Some theorists argue that common factors account for virtually *all* of the progress that clients make in therapy (Wampold, 2001). It seems more likely that the benefits of therapy represent the combined effects of common factors and specific procedures (Beutler & Harwood, 2002). Either way, it is clear that common factors play a significant role in insight therapy.

REVIEW of Key Points

15.3 Freudian approaches to therapy assume that neuroses originate from unresolved conflicts lurking in the unconscious. Therefore, in psychoanalysis free association (discussing whatever comes to mind with no censorship) and dream analysis are used to explore the unconscious.

15.4 When an analyst's probing hits sensitive areas, resistance, which involves unconscious defensive maneuvers to hinder progress, can be expected. The transference relationship may be used to overcome this resistance so that the client can handle interpretations that lead to insight.

15.5 Rogers's client-centered therapy assumes that neurotic anxieties are derived from incongruence between a person's self-concept and reality. Accordingly, the client-centered therapist emphasizes trying to provide a supportive climate marked by genuineness, unconditional positive regard, and empathy. The process of client-centered therapy depends on clarification of the client's feelings to promote self-acceptance.

15.6 The growth of the positive psychology movement has begun to inspire new approaches to insight therapy, such as

well-being therapy. Positive psychotherapy attempts to get clients to recognize their strengths, appreciate their blessings, savor positive experiences, and find meaning in their lives.

15.7 Participants in group therapy essentially act as therapists for one another, exchanging insights and emotional support. The therapist sets goals for the group and works to maintain a supportive climate. Group therapy is less expensive and has some advantages in comparison to individual therapy. People see that their problems are not unique, and they can work on social skills in a safe environment.

15.8 Evaluating the effectiveness of any approach to therapy is complex and difficult. Nonetheless, the weight of modern evidence suggests that insight therapies are superior to no treatment or to placebo treatment. Studies generally find the greatest improvement early in treatment. Much of the improvement seen in clients in therapy may be attributable to the operation of common factors, such as the development of a therapeutic alliance, the provision of emotional support, and the cultivation of hope.

Behavior Therapies

Behavior therapy is different from insight therapy in that behavior therapists make no attempt to help clients achieve grand insights about themselves. Why not? Because behavior therapists believe that such insights aren't necessary to produce constructive change. For example, consider a client troubled by compulsive gambling. The behavior therapist doesn't care whether this behavior is rooted in unconscious conflicts or parental rejection. What the

client needs is to get rid of the maladaptive behavior. Consequently, the therapist simply designs a program to eliminate the compulsive gambling.

The crux of the difference between insight therapy and behavior therapy is this: Insight therapists treat pathological symptoms as signs of an underlying problem, whereas behavior therapists think that the symptoms *are* the problem. Thus, ***behavior therapies* involve the application of learning**
Key Learning Goals

15.12 Evaluate the efficacy of behavior therapies.

principles to direct efforts to change clients' maladaptive behaviors.

Behaviorism has been an influential school of thought in psychology since the 1920s. Nevertheless, behaviorists devoted little attention to clinical issues until the 1950s, when behavior therapy emerged out of three independent lines of research fostered by B. F. Skinner and his colleagues (Skinner, Solomon, & Lindsley, 1953) in the United States; by Hans Eysenck (1959) and his colleagues in Britain; and by Joseph Wolpe (1958) and his colleagues in South Africa (Glass & Arnkoff, 1992). Since then, there has been an explosion of interest in behavioral approaches to psychotherapy.

Behavior therapies are based on certain assumptions (Berkowitz, 2003). *First, it is assumed that behavior is a product of learning.* No matter how self-defeating or pathological a client's behavior might be, the behaviorist believes that it is the result of past learning and conditioning. *Second, it is assumed that what has been learned can be unlearned.* The same learning principles that explain how the maladaptive behavior was acquired can be used to get rid of it. Thus, behavior therapists attempt to change clients' behavior by applying the principles of classical conditioning, operant conditioning, and observational learning.

Systematic Desensitization   11e

Devised by Joseph Wolpe (1958), systematic desensitization revolutionized psychotherapy by giving therapists their first useful alternative to traditional "talk therapy" (Fishman & Franks, 1992). *Systematic desensitization* **is a behavior therapy used to reduce phobic clients' anxiety responses through counterconditioning.** The treatment assumes that most anxiety responses are acquired through classical conditioning (as we discussed in Chapter 14). According to this model, a harmless stimulus (for instance, a bridge) may be paired with a fear-arousing event (lightning striking it) so that it becomes a conditioned stimulus eliciting anxiety. The goal of systematic desensitization is to weaken the association between the conditioned stimulus (the bridge) and the conditioned response of anxiety (see **Figure 15.8**). Systematic desensitization involves three steps.

In the first step, the therapist helps the client build an anxiety hierarchy. The hierarchy is a list of anxiety-arousing stimuli related to the specific source of anxiety, such as flying, academic tests, or snakes. The client ranks the stimuli from the least anxiety arousing to the most anxiety arousing. This ordered

Joseph Wolpe

"Neurotic anxiety is nothing but a conditioned response."

Figure 15.8

The logic underlying systematic desensitization. Behaviorists argue that many phobic responses are acquired through classical conditioning, as in the example diagrammed here. Systematic desensitization targets the conditioned associations between phobic stimuli and fear responses.

list of stimuli is the *anxiety hierarchy.* An example of an anxiety hierarchy for one woman's fear of heights is shown in **Figure 15.9**.

The second step involves training the client in deep muscle relaxation. This second phase may begin during early sessions while the therapist and client are still constructing the anxiety hierarchy. Various therapists use different relaxation training procedures. Whatever procedures are used, the client must learn to engage in deep, thorough relaxation on command from the therapist.

In the third step, the client tries to work through the hierarchy, learning to remain relaxed while imagining each stimulus. Starting with the least anxiety-arousing stimulus, the client imagines the situation as vividly as possible while relaxing. If the client experiences strong anxiety, he or she drops the imaginary scene and concentrates on relaxation. The client keeps repeating this process until he or she can imagine a scene with little or no anxiety. Once a particular scene is conquered, the client moves on to the next stimulus situation in the anxiety hierarchy. Gradually, over a number of therapy sessions, the client progresses through the hierarchy, unlearning troublesome anxiety responses.

As clients conquer *imagined* phobic stimuli, they may be encouraged to confront the *real* stimuli. Although desensitization to imagined stimuli *can* be effective by itself, contemporary behavior therapists usually follow it up with direct exposures to the real anxiety-arousing stimuli (Emmelkamp, 2004). Indeed, behavioral interventions emphasizing direct exposures to anxiety-arousing situations have become behavior therapists' treatment of choice for phobic and other anxiety disorders. Usually, these real-life confrontations prove harmless, and individuals' anxiety responses decline.

According to Wolpe (1958, 1990), the principle at work in systematic desensitization is simple. Anxi-

Systematic desensitization is a behavioral treatment for phobias. Early studies of the procedure's efficacy often used people who had snake phobias as research subjects because people with snake phobias were relatively easy to find. This research showed that systematic desensitization is generally an effective treatment.

ety and relaxation are incompatible responses. The trick is to recondition people so that the conditioned stimulus elicits relaxation instead of anxiety. This is *counterconditioning*—an attempt to reverse the process of classical conditioning by associating the crucial stimulus with a new conditioned response. Although Wolpe's explanation of how systematic desensitization works has been questioned, the technique's effectiveness in eliminating specific anxieties has been well documented (Spiegler & Guevremont, 2003).

Aversion Therapy 11e

Aversion therapy is far and away the most controversial of the behavior therapies. It's not something that you would sign up for unless you were pretty desperate. Psychologists usually suggest it only as a treatment of last resort, after other interventions have failed. What's so terrible about aversion therapy? The client has to endure decidedly unpleasant stimuli, such as shocks or drug-induced nausea. *Aversion therapy* is a behavior therapy in which an aversive stimulus is paired with a stimulus that elicits an undesirable response. For example, alcoholics have had an *emetic drug* (one that causes nausea and vomiting) paired with their favorite drinks during therapy sessions (Landabaso et al., 1999). By pairing the drug with alcohol, the therapist hopes to create a conditioned aversion to alcohol (see **Figure 15.10**).

Aversion therapy takes advantage of the automatic nature of responses produced through classical conditioning. Admittedly, alcoholics treated with aversion therapy know that they won't be given an emetic outside of their therapy sessions. However, their reflex response to the stimulus of alcohol may

An Anxiety Hierarchy for Systematic Desensitization

Degree of fear	
5	I'm standing on the balcony of the top floor of an apartment tower.
10	I'm standing on a stepladder in the kitchen to change a light bulb.
15	I'm walking on a ridge. The edge is hidden by shrubs and treetops.
20	I'm sitting on the slope of a mountain, looking out over the horizon.
25	I'm crossing a bridge 6 feet above a creek. The bridge consists of an 18-inch-wide board with a handrail on one side.
30	I'm riding a ski lift 8 feet above the ground.
35	I'm crossing a shallow, wide creek on an 18-inch-wide board, 3 feet above water level.
40	I'm climbing a ladder outside the house to reach a second-story window.
45	I'm pulling myself up a 30-degree wet, slippery slope on a steel cable.
50	I'm scrambling up a rock, 8 feet high.
55	I'm walking 10 feet on a resilient, 18-inch-wide board, which spans an 8-foot-deep gulch.
60	I'm walking on a wide plateau, 2 feet from the edge of a cliff.
65	I'm skiing an intermediate hill. The snow is packed.
70	I'm walking over a railway trestle.
75	I'm walking on the side of an embankment. The path slopes to the outside.
80	I'm riding a chair lift 15 feet above the ground.
85	I'm walking up a long, steep slope.
90	I'm walking up (or down) a 15-degree slope on a 3-foot-wide trail. On one side of the trail the terrain drops down sharply; on the other side is a steep upward slope.
95	I'm walking on a 3-foot-wide ridge. The slopes on both sides are long and more than 25 degrees steep.
100	I'm walking on a 3-foot-wide ridge. The trail slopes on one side. The drop on either side of the trail is more than 25 degrees.

Figure 15.9

Example of an anxiety hierarchy. Systematic desensitization requires the construction of an anxiety hierarchy like the one shown here, which was developed for a woman who had a fear of heights but wanted to go hiking in the mountains.

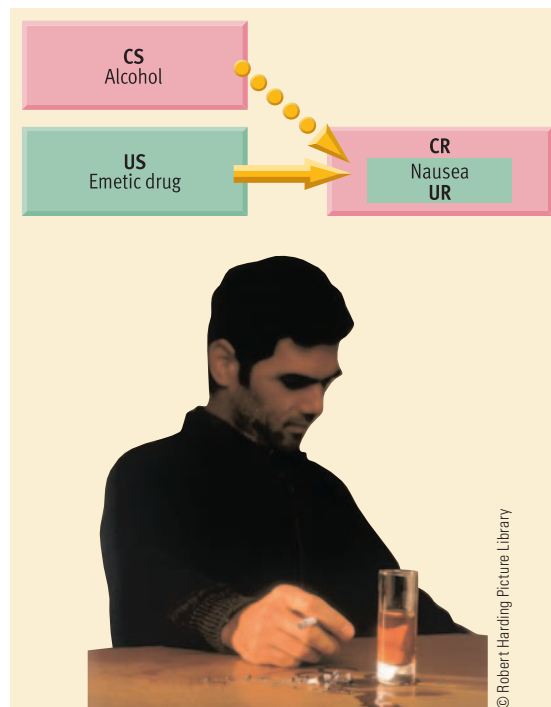

Figure 15.10

Aversion therapy. Aversion therapy uses classical conditioning to create an aversion to a stimulus that has elicited problematic behavior. For example, in the treatment of drinking problems, alcohol may be paired with a nausea-inducing drug to create an aversion to drinking.

be changed so they respond to it with nausea and distaste (remember the power of conditioned taste aversions described in Chapter 6?). Obviously, this response should make it much easier to resist the urge to drink.

Aversion therapy is not a widely used technique, and when it is used it is usually only one element in a larger treatment program. Troublesome behaviors treated successfully with aversion therapy have included drug and alcohol abuse, sexual deviance, gambling, shoplifting, stuttering, cigarette smoking, and overeating (Bordnick et al., 2004; Emmelkamp, 1994; Grossman & Ruiz, 2004; Maletzky, 2002).

Social Skills Training

Many psychological problems grow out of interpersonal difficulties. Behavior therapists point out that people are not born with social finesse—they acquire social skills through learning. Unfortunately, some people have not learned how to be friendly, how to make conversation, how to express anger appropriately, and so forth. Social ineptitude can contribute to anxiety, feelings of inferiority, and various kinds of disorders. In light of these findings, therapists are increasingly using social skills training in efforts to improve clients' social abilities. This approach to therapy has yielded promising results in the treatment of social anxiety (Herbert et al., 2005), autism (Scattone, 2007), attention deficit disorder (Monastra, 2008) and schizophrenia (Granholm et al., 2008).

Social skills training **is a behavior therapy designed to improve interpersonal skills that emphasizes modeling, behavioral rehearsal, and shaping.** This type of behavior therapy can be conducted with individual clients or in groups. Social skills training depends on the principles of operant conditioning and observational learning. With *modeling,* the client is encouraged to watch socially skilled friends and colleagues in order to acquire appropriate responses (eye contact, active listening, and so on) through observation. In *behavioral rehearsal,* the client tries to practice social techniques in structured role-playing exercises. The therapist provides corrective feedback and uses approval to reinforce progress. Eventually, of course, clients try their newly acquired skills in real-world interactions. Usually, they are given specific homework assignments. *Shaping* is used in that clients are gradually asked to handle more complicated and delicate social situations. For example, a nonassertive client may begin by working on making requests

of friends. Only much later will he be asked to tackle standing up to his boss at work.

Cognitive-Behavioral Treatments

In Chapter 14, we learned that cognitive factors play a key role in the development of many anxiety and mood disorders. Citing the importance of such findings, in the 1970s behavior therapists started to focus more attention on their clients' cognitions (Arnkoff & Glass, 1992; Hollon & Beck, 2004). *Cognitive-behavioral treatments* **use varied combinations of verbal interventions and behavior modification techniques to help clients change maladaptive patterns of thinking.** Some of these treatments, such as Albert Ellis's (1973) *rational-emotive behavior therapy* and Aaron Beck's (1976) *cognitive therapy,* emerged out of an insight therapy tradition, whereas other treatments, such as the systems developed by Donald Meichenbaum (1977) and Michael Mahoney (1974), emerged from the behavioral tradition. Here we will focus on Beck's cognitive therapy as an example of a cognitive-behavioral treatment (see Chapter 13 for a discussion of some of Ellis's ideas).

Cognitive therapy **uses specific strategies to correct habitual thinking errors that underlie various types of disorders.** In recent years cognitive therapy has been applied fruitfully to a wide range of disorders (Grant, Young, & DeRubeis, 2005; Hollon, Stewart, & Strunk, 2006), but it was originally devised as a treatment for depression. According to cognitive therapists, depression is caused by "errors" in thinking (see **Figure 15.11**). They assert that depression-prone people tend to (1) blame their setbacks on personal inadequacies without considering

Negative thinking

- Blame setbacks on personal inadequacies
- Focus selectively on negative events
- Make unduly pessimistic projections about future
- Draw negative conclusions about personal worth

→ Increased vulnerability to depression

Figure 15.11

Beck's view of the roots of disorders. Beck's theory initially focused on the causes of depression, although it was gradually broadened to explain other disorders. According to Beck, depression is caused by the types of negative thinking shown here.

Aaron Beck

"Most people are barely aware of the automatic thoughts which precede unpleasant feelings or automatic inhibitions."

Association for Behavioral and Cognitive Therapies

The website for this professional organization has a variety of resources that are relevant to the general public. The most valuable of these resources are the fact sheets on cognitive-behavioral treatments for over 40 common problems and disorders. These fact sheets explain how cognitive-behavioral interventions can be used in the treatment of alcohol abuse, autism, chronic fatigue, eating disorders, insomnia, phobias, schizophrenia, shyness, and a host of other conditions.

circumstantial explanations, (2) focus selectively on negative events while ignoring positive events, (3) make unduly pessimistic projections about the future, and (4) draw negative conclusions about their worth as a person based on insignificant events. For instance, imagine that you got a low grade on a minor quiz in a class. If you made the kinds of errors in thinking just described, you might blame the grade on your woeful stupidity, dismiss comments from a classmate that it was an unfair test, gloomily predict that you will surely flunk the course, and conclude that you are not genuine college material.

The goal of cognitive therapy is to change clients' negative thoughts and maladaptive beliefs (Kellogg & Young, 2008). To begin, clients are taught to detect their automatic negative thoughts. These are self-defeating statements that people are prone to make when analyzing problems. Examples might include "I'm just not smart enough," "No one really likes me," or "It's all my fault." Clients are then trained to subject these automatic thoughts to reality testing. The therapist helps them to see how unrealistically negative the thoughts are.

Cognitive therapy uses a variety of behavioral techniques, such as modeling, systematic monitoring of one's behavior, and behavioral rehearsal (Wright, Beck, & Thase, 2003), Cognitive therapists often give their clients "homework assignments" that focus on changing clients' overt behaviors. Clients may be instructed to engage in overt responses on their own, outside of the clinician's office. For example, one shy, insecure young man in cognitive therapy was told to go to a singles bar and engage three different women in conversations for up to five minutes each (Rush, 1984). He was instructed to record his thoughts before and after each of the conversations. This assignment elicited various maladaptive patterns of thought that gave the young man and his therapist plenty to work on in subsequent sessions.

How Effective Are Behavior Therapies?

Behavior therapists have historically placed more emphasis on the importance of measuring therapeutic outcomes than insight therapists have. Thus, there is ample evidence attesting to the effectiveness of behavior therapy (Jacob & Pelham, 2005). Of course, behavior therapies are not well suited to the treatment of some types of problems (vague feelings of discontent, for instance). Furthermore, it's misleading to make global statements about the

effectiveness of behavior therapies, because they include many types of procedures designed for very different purposes. For example, the value of systematic desensitization for phobias has no bearing on the value of aversion therapy for sexual deviance. For our purposes, it is sufficient to note that there is favorable evidence on the efficacy of most of the widely used behavioral interventions (Zinbarg & Griffith, 2008). Behavior therapies can make important contributions to the treatment of phobias, obsessive-compulsive disorders, sexual dysfunction, schizophrenia, drug-related problems, eating disorders, psychosomatic disorders, hyperactivity, autism, and mental retardation (Berkowitz, 2003; Emmelkamp, 2004).

REVIEW of Key Points

15.9 Behavior therapies use the principles of learning in direct efforts to change specific aspects of behavior. Wolpe's systematic desensitization is a treatment designed to relieve phobias. It involves the construction of an anxiety hierarchy, relaxation training, and step-by-step movement through the hierarchy, pairing relaxation with each phobic stimulus.

15.10 In aversion therapy, a stimulus associated with an unwanted response is paired with an unpleasant stimulus in an effort to eliminate the maladaptive response. Social skills training can improve clients' interpersonal skills through shaping, modeling, and behavioral rehearsal.

15.11 Cognitive-behavioral treatments concentrate on changing the way clients think about events in their lives. Cognitive therapists reeducate clients to detect and challenge automatic negative thoughts that cause depression and anxiety. Cognitive therapy also depends on modeling, behavioral rehearsal, and homework assignments.

15.12 Behavior therapists have historically placed more emphasis on the importance of measuring therapeutic outcomes than insight therapists have. There is ample evidence that behavior therapies are effective in the treatment of a wide variety of disorders.

Key Learning Goals

15.13 Summarize the therapeutic actions and side effects of antianxiety and antipsychotic drugs.

15.14 Summarize the therapeutic actions and side effects of antidepressant and mood stabilizing drugs.

15.15 Evaluate the overall efficacy of drug treatments and controversies surrounding pharmaceutical research.

15.16 Describe electroconvulsive therapy and assess its therapeutic effects and risks.

15.17 Describe the therapeutic use of transcranial magnetic stimulation and direct brain stimulation.

Biomedical Therapies

In the 1950s, a French surgeon looking for a drug that would reduce patients' autonomic response to surgical stress noticed that chlorpromazine produced a mild sedation. Based on this observation, Delay and Deniker (1952) decided to give chlorpromazine to hospitalized schizophrenic patients. They wanted to see whether the drug would have calming effects. Their experiment was a dramatic success. Chlorpromazine became the first effective antipsychotic drug, and a revolution in psychiatry was begun. Hundreds of thousands of severely disturbed patients who had appeared doomed to spend the remainder of their lives in mental hospitals were gradually sent home, thanks to the therapeutic effects of antipsychotic drugs. Today, biomedical therapies such as drug treatment lie at the core of psychiatric practice.

Biomedical therapies are physiological interventions intended to reduce symptoms associated with psychological disorders. These therapies assume that psychological disorders are caused, at least in part, by biological malfunctions. As we discussed in the previous chapter, this assumption clearly has merit for many disorders, especially the more severe ones. We will discuss the two standard biomedical approaches to psychotherapy, drug therapy and electroconvulsive (shock) therapy, and then delve into some experimental, new treatments involving brain stimulation.

Treatment with Drugs

Psychopharmacotherapy is the treatment of mental disorders with medication. We will refer to this kind of treatment more simply as *drug therapy.* The four main categories of therapeutic drugs for psychological problems are (1) antianxiety drugs, (2) antipsychotic drugs, (3) antidepressant drugs, and (4) mood-stabilizing drugs.

Antianxiety Drugs

Many people routinely pop pills to relieve anxiety. The drugs involved in this common coping strategy are *antianxiety drugs, which relieve tension, apprehension, and nervousness.* The most popular of these drugs are Valium and Xanax. These are the trade names (the proprietary names that pharmaceutical companies use in marketing drugs) for diazepam and alprazolam, respectively.

Valium, Xanax, and other drugs in the *benzodiazepine* family are often called *tranquilizers.* These drugs exert their effects almost immediately, and they can be fairly effective in alleviating feelings of anxiety (Dubovsky, 2005). However, their effects are measured in hours, so their impact is relatively short-lived. Antianxiety drugs are routinely prescribed for people with anxiety disorders, but they are also given to millions of people who simply suffer from chronic nervous tension.

All the drugs used to treat psychological problems have potentially troublesome side effects that show up in some patients but not others. The antianxiety drugs are no exception. The most common side effects of Valium and Xanax are listed in Table 15.1. Some of these side effects—such as drowsiness, depression, nausea, and confusion—present serious problems for some patients. These drugs also have potential for abuse, drug dependence, and overdose, although these risks have probably been exaggerated in the press (Ballenger, 2000; Silberman, 1998). Another drawback is that patients who have been on antianxiety drugs for a while often experience withdrawal symptoms when their drug treatment is stopped (Raj & Sheehan, 2004).

Antipsychotic Drugs

Antipsychotic drugs are used primarily in the treatment of schizophrenia. They are also given to people with severe mood disorders who become delusional.

Table 15.1 Side Effects of Xanax and Valium

Side Effects	Patients Experiencing Side Effects (%)	
	Xanax	Valium
Drowsiness	36.0	49.4
Lightheadedness	18.6	24.0
Dry mouth	14.9	13.0
Depression	11.9	17.0
Nausea, vomiting	9.3	10.0
Constipation	9.3	11.3
Insomnia	9.0	6.7
Confusion	9.3	14.1
Diarrhea	8.5	10.5
Tachycardia, palpitations	8.1	7.2
Nasal congestion	8.1	7.2
Blurred vision	7.0	9.1

The trade (and generic) names of some classic drugs in this category are Thorazine (chlorpromazine), Mellaril (thioridazine), and Haldol (haloperidol). ***Antipsychotic drugs* are used to gradually reduce psychotic symptoms, including hyperactivity, mental confusion, hallucinations, and delusions.** The traditional antipsychotics appear to decrease activity at certain subtypes of dopamine synapses, although the exact relationship between their neurochemical effects and their clinical effects remains obscure (Egan & Hyde, 2000; Miyamoto et al., 2003).

Studies suggest that antipsychotics reduce psychotic symptoms in about 70% of patients, albeit in varied degrees (Kane & Marder, 2005). When antipsychotic drugs are effective, they work their magic gradually, as shown in **Figure 15.12**. Patients usually begin to respond within one to three weeks, but considerable variability in responsiveness is seen (Emsley, Rabinowitz, & Medori, 2006). Further improvement may occur for several months. Many schizophrenic patients are placed on antipsychotics indefinitely, because these drugs can reduce the likelihood of a relapse into an active schizophrenic episode (Marder & van Kammen, 2005).

Antipsychotic drugs undeniably make a huge contribution to the treatment of severe mental disorders, but they are not without problems. They have many unpleasant side effects (Cohen, 1997; Wilkaitis, Mulvihill, & Nasrallah, 2004). Drowsiness, constipation, and cotton mouth are common. The drugs may also produce effects that resemble the symptoms of Parkinson's disease, including muscle tremors, muscular rigidity, and impaired motor coordination. After being released from a hospital, many schizophrenic patients discontinue their drug regimen because of the disagreeable side effects. Unfortunately, a relapse eventually occurs in most patients after they stop taking antipsychotic medication (Gitlin et al., 2001). In addition to minor side effects, antipsychotics may cause a severe and lasting problem called *tardive dyskinesia,* which is seen in about 20% of patients who receive long-term treatment with traditional antipsychotics (Miyamoto et al., 2003). ***Tardive dyskinesia* is a neurological disorder marked by involuntary writhing and ticlike movements of the mouth, tongue, face, hands, or feet.** Once this debilitating syndrome emerges, there is no cure, although spontaneous remission sometimes occurs after the discontinuation of antipsychotic medication (Pi & Simpson, 2000).

Psychiatrists are currently enthusiastic about a new class of antipsychotic agents called *atypical antipsychotic drugs* (such as clozapine, olanzapine, and quetiapine). These drugs are roughly as effective as traditional antipsychotics (Fleischhacker, 2002), and
they can help some patients who do not respond to conventional antipsychotic medications (Volavka et al., 2002). Moreover, the atypical antipsychotics produce fewer unpleasant side effects and carry less risk for tardive dyskinesia (Correll, Leucht, & Kane, 2004; Lieberman et al., 2003). Of course, like all powerful drugs, they carry some risks, as they appear to increase patients' vulnerability to diabetes and cardiovascular problems (Meltzer et al., 2002).

Although they are much more expensive than traditional antipsychotics, the atypical antipsychotics have become the first line of defense in the treatment of schizophrenia (van Kammen & Marder, 2005). However, recent research has generated some controversy regarding this trend. These studies have found that the newer antipsychotics aren't any more effective than the older medications in reducing symptoms and that the side effects of the newer drugs are only marginally less troublesome than the side effects of the older drugs (Lieberman et al., 2005; Stroup, Kraus, & Marder, 2006). These findings raise vexing, complicated questions about the cost effectiveness of psychiatrists' reliance on the newer medications (Lieberman, 2006; Rosenheck, 2006).

Antidepressant Drugs   11e

As their name suggests, ***antidepressant drugs* gradually elevate mood and help bring people out of a depression.** Prior to 1987, there were two principal classes of antidepressants: *tricyclics* (such as Elavil) and *MAO inhibitors* (such as Nardil). These two sets of drugs affect neurochemical activity in different ways

Figure 15.12

The time course of antipsychotic drug effects.
Antipsychotic drugs reduce psychotic symptoms gradually, over a span of weeks, as graphed here. In contrast, patients given placebo medication show little improvement.

SOURCE: Cole, J. O., Goldberg, S. C., & Davis, J. M. (1966). Drugs in the treatment of psychosis. In P. Solomon (Ed.), *Psychiatric drugs.* New York: Grune & Stratton. From data in the NIMH-PSC Collaborative Study I. Reprinted by permission of J. M. Davis.

Serotonin norepinephrine reuptake inhibitors (SNRIs) selectively slow reuptake at serotonin and norepinephrine synapses, thus increasing activation in both systems.

Trycyclic antidepressants inhibit reuptake at serotonin and norepinephrine synapses, which elevates activity at both types of synapses. Tricyclics also blockade activity at several subtypes of postsynaptic receptors.

Selective serotonin reuptake inhibitors (SSRIs) slow reuptake at serotonin synapses, so activity is increased only at serotonin synapses.

MAO inhibitors work by disabling MAO enzymes that would normally metabolize and inactivate neurotransmitters at dopamine, norepinephrine, and serotonin synapses.
(see **Figure 15.13**) and tend to work with different patients. Overall, they are beneficial for about two-thirds of depressed patients (Gitlin, 2002), although only about one-third of treated patients experience a *complete resolution* of their symptoms (Shulman, 2001). The tricylics have fewer problems with side effects and complications than the MAO inhibitors (Potter et al., 2006). Like antipsychotic drugs, antidepressants exert their effects gradually over a period of weeks.

Today, psychiatrists are more likely to prescribe a newer class of antidepressants, called *selective serotonin reuptake inhibitors (SSRIs),* which slow the reuptake process at serotonin synapses, thus increasing serotonin activation. The drugs in this class, which include Prozac (fluoxetine), Paxil (paroxetine), and Zoloft (sertraline), seem to yield therapeutic gains similar to the tricyclics in the treatment of depression (Shelton & Lester, 2006) while producing fewer unpleasant or dangerous side effects (Kelsey, 2005). SSRIs have also proven valuable in the treatment of obsessive-compulsive disorders, panic disorders, and other anxiety disorders (Rivas-Vazquez, 2001). However, there is some doubt about how effective the SSRIs (and other antidepressants) are in relieving episodes of depression among patients suffering from bipolar disorder (Thase, 2005). Bipolar patients do not seem to respond as well as those who suffer from depression only. And in some cases antidepressants appear to foster a switch back into a manic episode (Altshuler et al., 2006).

A major concern in recent years has been evidence from a number of studies that SSRIs may increase the risk for suicide, primarily among adolescents and young adults (Healy & Whitaker, 2003; Holden, 2004). The challenge of collecting definitive data on this issue is much more daunting than one

might guess, in part because suicide rates are already elevated among people who exhibit the disorders for which SSRIs are prescribed (Rihmer, 2003; Wessely & Kerwin, 2004). Some researchers have collected data that suggest that suicide rates have *declined* slightly because of widespread prescription of SSRIs (Baldessarini et al., 2007; Gibbons et al., 2006), while others have found no association between SSRIs and suicide (Lapiere, 2003; Simon et al., 2006).

Overall, however, when antidepressants are compared to placebo treatment, the data suggest that antidepressants lead to a slight elevation in the risk of suicidal behavior, from roughly 2% to 4% (Bridge et al., 2007; Dubicka, Hadley, & Roberts, 2006; Hammad, Laughren, & Racoosin, 2006). The increased suicide risk appears to mainly be a problem among a small minority of children and adolescents in the first month after starting antidepressants, especially during the first nine days (Jick, Kaye, & Jick, 2004). Thus, patients starting on SSRIs should be carefully monitored by their physicians and families (Culpepper et al., 2004). Regulatory warnings from the U.S. Food and Drug Administration (FDA) have led to a decline in the prescription of SSRIs among adolescents (Nemeroff et al., 2007). This trend has prompted concern that increases in suicide may occur among untreated individuals. This concern seems legitimate in that suicide risk clearly peaks in the month prior to people beginning treatment for depression, whether that treatment involves SSRIs or psychotherapy (see **Figure 15.14**; Simon & Savarino, 2007). This pattern presumably occurs because the escalating agony of depression finally prompts people to seek treatment, but it also suggests that getting treatment with drugs or therapy reduces suicidal risk. In the final analysis, this is a complex issue, but the one thing experts
Figure 15.14

Probability of a suicide attempt in relation to the initiation of treatment. Examining medical records for thousands of patients, Simon and Savarino (2007) were able to gather information on the likelihood of a suicide attempt in the months before and after commencing treatment for depression. They compared patients who were put on an antidepressant medication against those who started in some form of insight or behavioral therapy. The data shown here, for young patients under the age of 25, indicate that suicide risk is highest in the month prior to treatment and next highest in the month after treatment is begun for both groups. These findings suggest that elevated suicide rates are not unique to starting on antidepressants and that getting treatment (whether it is medication or psychotherapy) reduces the risk of suicide.

seem to agree on is that adolescents starting on SSRIs should be monitored closely.

The newest class of antidepressants consists of medications that inhibit reuptake at both serotonin and norepinephrine synapses, referred to as SNRIs. The first two drugs in this category are venlafaxine (Effexor) and duloxetine (Celexa). These drugs appear to produce slightly stronger antidepressant effects than the SSRIs (Thase & Denko, 2008). However, targeting two neurotransmitter systems also leads to a broader range of side effects, including troublesome elevations in blood pressure (Thase & Sloan, 2006).

Mood Stabilizers

Mood stabilizers **are drugs used to control mood swings in patients with bipolar mood disorders.** For many years, lithium was the only effective drug in this category. Lithium has proven valuable in preventing *future* episodes of both mania and depression in patients with bipolar illness (Geddes et al., 2004). Lithium can also be used in efforts to bring patients with bipolar illness out of *current* manic or depressive episodes (Keck & McElroy, 2006). However, antipsychotics and antidepressants are more commonly used for these purposes. On the negative side of the ledger, lithium does have some dangerous side effects if its use isn't managed skillfully (Jefferson & Greist, 2005). Lithium levels in the patient's blood must be monitored carefully, because high concentrations can be toxic and even fatal. Kidney and thyroid gland complications are the other major problems associated with lithium therapy.

In recent years a number of alternatives to lithium have been developed. The most popular of these newer mood stabilizers is an anticonvulsant agent called *valproate,* which has become more widely used than lithium in the treatment of bipolar disorders (Thase & Denko, 2008). Valproate appears to be roughly as effective as lithium in efforts to treat current manic episodes and to prevent future affective disturbances (Moseman et al., 2003). The advantage provided by valproate is that it has fewer side effects than lithium and is better tolerated by patients (Bowden, 2004).

How Effective Are Drug Therapies?

Drug therapies can produce clear therapeutic gains for many kinds of patients. What's especially impressive is that they can be effective with disorders that otherwise defy therapeutic endeavors. Nonetheless, drug therapies are controversial. Critics of drug therapy have raised a number of issues (Breggin & Cohen, 2007; Healy, 2004; Lickey & Gordon, 1991; Whitaker, 2002). First, some critics argue that drug therapies are not as effective as advertised and that they often produce superficial, short-lived curative effects. For example, Valium does not really solve problems with anxiety; it merely provides temporary relief from an unpleasant symptom. Moreover, relapse rates are substantial when drug regimens are discontinued. Second, critics charge that many drugs are overprescribed and many patients overmedicated. According to these critics, a number of physicians routinely hand out prescriptions without giving adequate consideration to more complicated and

Dr. Bob's Psychopharmacology Tips

Psychopharmacology is the use of medication to treat psychological disorders. Physician and pharmacology specialist Robert Hsiang (University of Chicago) provides both broad and specific references about the interface of drugs and the human mind, including a searchable archive of professional information.

"I medicate first and ask questions later."

difficult interventions. Third, some critics charge that the damaging side effects of therapeutic drugs are underestimated by psychiatrists and that these side effects are often worse than the illnesses that the drugs are supposed to cure. Citing problems such as tardive dyskinesia, lithium toxicity, and addiction to antianxiety agents, these critics argue that the risks of therapeutic drugs aren't worth the benefits.

Critics maintain that the negative effects of psychiatric drugs are not fully appreciated because the pharmaceutical industry has managed to gain undue influence over the research enterprise as it relates to drug testing (Angell, 2000, 2004; Healy, 2004; Weber, 2006). Today, most researchers who investigate the benefits and risks of medications and write treatment guidelines have lucrative financial arrangements with the pharmaceutical industry (Bodenheimer, 2000; Choudhry, Stelfox, & Detsky, 2002; Lurie et al., 2006). Their studies are funded by drug companies, and they often receive substantial consulting fees. These financial arrangements have become so common, the prestigious *New England Journal of Medicine* had to relax its conflict-of-interest rules because it had difficulty finding expert reviewers who did not have financial ties to the drug industry (Drazen & Curfman, 2002). Unfortunately, these financial ties appear to undermine the objectivity required in scientific research, as studies funded by drug companies are far less likely to report unfavorable results than nonprofit-funded studies (Bekelman, Li, & Gross, 2003; Perlis et al., 2005; Rennie & Luft, 2000). Consistent with this finding, when specific antipsychotic drugs are pitted against each other in clinical trials, the sponsoring company's drug is reported to be superior to the other drugs in 90% of studies (Heres et al., 2006). Industry-financed drug trials also tend to be much too brief to detect the long-term risks associated with new drugs, and when unfavorable results emerge, the data are often withheld from publication (Antonuccio, Danton, &

McClanahan, 2003). Also, research designs are often slanted in a multitude of ways so as to exaggerate the positive effects and minimize the negative effects of the drugs under scrutiny (Carpenter, 2002; Chopra, 2003; Moncrieff, 2001). The conflicts of interest that appear to be pervasive in contemporary drug research raise grave concerns that require attention from researchers, universities, and federal agencies.

Obviously, drug therapies have stirred up some debate. However, this controversy pales in comparison to the furious debates inspired by electroconvulsive (shock) therapy (ECT). ECT is so controversial that the residents of Berkeley, California, voted in 1982 to outlaw ECT in their city. However, in subsequent lawsuits, the courts ruled that scientific questions cannot be settled through a vote, and they overturned the law. What makes ECT so controversial? You'll see in the next section.

Electroconvulsive Therapy (ECT)

In the 1930s, a Hungarian psychiatrist named Ladislas von Meduna speculated that epilepsy and schizophrenia could not coexist in the same body. On the basis of this observation, which turned out to be inaccurate, von Meduna theorized that it might be useful to induce epileptic-like seizures in schizophrenic patients. Initially, a drug was used to trigger these seizures. However, by 1938 a pair of Italian psychiatrists (Cerletti & Bini, 1938) demonstrated that it was safer to elicit the seizures with electric shock. Thus, modern electroconvulsive therapy was born.

Electroconvulsive therapy **(ECT) is a biomedical treatment in which electric shock is used to produce a cortical seizure accompanied by convulsions.** In ECT, electrodes are attached to the skull over the temporal lobes of the brain (see the photo on the facing page). A light anesthesia is induced, and the patient is given a variety of drugs to minimize the likelihood of complications. An electric current is then applied either to the right side or to both sides of the brain for about a second. Unilateral shock delivered to the right hemisphere is the preferred method of treatment today (Abrams, 2000). The current triggers a brief (about 30 seconds) convulsive seizure. The patient normally awakens in an hour or two and manifests some confusion, disorientation, and nausea, which usually clear up in a matter of hours. People typically receive between 6 and 12 treatments over a period of a month or so (Glass, 2001).

The clinical use of ECT peaked in the 1940s and 1950s, before effective drug therapies were widely

This patient is being prepared for electroconvulsive therapy. The mouthpiece keeps the patient from biting her tongue during the electrically induced seizures.

available. ECT has long been controversial, and its use did decline in the 1960s and 1970s. Nonetheless, the use of ECT has seen a resurgence in recent decades. Although only about 8% of psychiatrists administer ECT, it is not a rare form of treatment (Hermann et al., 1998). Some critics argue that ECT is overused because it is a lucrative procedure that boosts psychiatrists' income while consuming relatively little of their time in comparison to insight therapy (Frank, 1990). Conversely, some ECT advocates argue that ECT is underutilized because the public harbors many misconceptions about its effects and risks (McDonald et al., 2004). Although ECT is used in the treatment of a variety of disorders, in recent decades it has primarily been recommended for the treatment of depression.

Effectiveness of ECT

The evidence on the therapeutic efficacy of ECT is open to varied interpretations. Proponents maintain that it is a remarkably effective treatment for major depression (Prudic, 2005; Rudorfer, Henry, & Sackeim, 2003). Moreover, they note that many patients who do not benefit from antidepressant medication improve in response to ECT (Nobler & Sackeim, 2006). However, opponents argue that the available studies are flawed and inconclusive and that ECT is probably no more effective than a placebo (Rose et al., 2003). Overall, there does seem to be enough favorable evidence to justify *conservative* use of ECT in treating severe mood disorders in patients who have not responded to medication (Carney & Geddes, 2003; Metzger, 1999). Unfortunately, relapse rates after ECT are distressingly high. Over 50% of patients relapse within 6 to 12 months, although re-

lapse rates can be reduced by giving ECT patients antidepressant drugs (Sackeim et al., 2001).

Curiously, to the extent that ECT may be effective, no one is sure why. The discarded theories about how ECT works could fill several books. Many ECT advocates theorize that the treatment must affect neurotransmitter activity in the brain. However, the evidence supporting this view is fragmentary, inconsistent, and inconclusive (Abrams, 1992; Kapur & Mann, 1993). ECT opponents have a radically different, albeit equally unproven, explanation for why ECT might *appear* to be effective: They maintain that some patients find ECT so aversive that they muster all their willpower to climb out of their depression to avoid further ECT treatments.

Risks Associated with ECT

Even ECT proponents acknowledge that memory losses, impaired attention, and other cognitive deficits are common short-term side effects of electroconvulsive therapy (Lisanby et al., 2000; Sackeim et al., 2007). However, ECT proponents assert that these deficits are mild and usually disappear within a month or two (Glass, 2001). An American Psychiatric Association (2001) task force concluded that there is no objective evidence that ECT causes structural damage in the brain or that it has any lasting negative effects on the ability to learn and remember information. In contrast, ECT critics maintain that ECT-induced cognitive deficits are often significant and sometimes permanent (Breggin, 1991; Rose et al., 2003), although their evidence seems to be largely anecdotal. Given the concerns about the risks of ECT and the doubts about its efficacy, it appears that the use of ECT will remain controversial for some time to come.

Understanding Biomedical Therapies

Check your understanding of biomedical therapies by matching each treatment with its chief use. The answers are in Appendix A.

Treatment

_____ **1.** Antianxiety drugs

_____ **2.** Antipsychotic drugs

_____ **3.** Antidepressant drugs

_____ **4.** Mood stabilizers

_____ **5.** Electroconvulsive therapy (ECT)

Chief purpose

a. To reduce psychotic symptoms

b. To bring a major depression to an end

c. To suppress tension, nervousness, and apprehension

d. To prevent future episodes of mania or depression in bipolar disorders

New Brain Stimulation Techniques

Scientists are always on the lookout for new methods of treating psychological disorders that might exhibit greater efficacy or fewer complications than ECT and drug treatments. Some new approaches to treatment involving stimulation of the brain are being explored with promising results, although they remain highly experimental at this time.

One new approach is *transcranial magnetic stimulation,* which was discussed in Chapter 3 as a method for studying brain function. **Transcranial magnetic stimulation (TMS) is a technique that permits scientists to temporarily enhance or depress activity in a specific area of the brain.** In TMS, a magnetic coil mounted on a small paddle is held over specific areas of the head to increase or decrease activity in discrete regions of the cortex (Nahas et al., 2007). Neuroscientists are mostly experimenting with TMS as a treatment for depression. Thus far, treatments delivered to the right and left prefrontal cortex show promise in reducing depressive symptoms (Nobler & Sackeim, 2006; O'Reardon et al., 2007). TMS generally is well tolerated, with minimal side effects. But a great deal of additional research will be necessary before the therapeutic value of TMS can be determined.

The other new approach to treatment is *deep brain stimulation.* **In *deep brain stimulation (DBS)* a thin electrode is surgically implanted in the brain and connected to an implanted pulse generator so that various electrical currents can be delivered to brain tissue adjacent to the electrode** (George, 2003; see **Figure 15.15**). DBS has proven valuable in the treatment of the motor disturbances associated with Parkinson's disease, tardive dyskinesia, and some seizure disorders (Halpern et al., 2007; Wider et al., 2008). Researchers are currently explor-

ing whether DBS may have value in the treatment of depression or obsessive-compulsive disorder (George et al., 2006; Hardesty & Sackeim, 2007). Obviously, this highly invasive procedure requiring brain surgery will never be a frontline therapy for mental disorders, but scientists hope that it may prove valuable for highly treatment-resistant patients who do not benefit from conventional therapies (Kuehn, 2007).
Figure 15.15

Deep brain stimulation. Deep brain stimulation requires a surgical procedure in which a thin electrode (about the width of a human hair) is inserted into deep areas of the brain. The electrode is connected to a pulse generator implanted under the skin of the chest. The placement of the electrode and the type of current generated depend on what condition is being treated. The electrode shown here was implanted in a motor area of the brain to treat the tremors associated with Parkinson's disease. Researchers are experimenting with other electrode placements in efforts to treat depression and obsessive-compulsive disorder.

REVIEW of Key Points

15.13 Antianxiety drugs exert their effects quickly and are fairly effective in reducing feelings of anxiety, but their impact is short-lived. They produce some nuisance side effects, and there can be complications involving abuse, dependence, and overdose. Antipsychotic drugs are used primarily in the treatment of schizophrenia. They reduce psychotic symptoms in about 70% of patients. Traditional antipsychotics can have a variety of serious side effects, which have been reduced in the newer, atypical antipsychotics.

15.14 Antidepressants are used to bring people out of episodes of depression. SSRIs are the dominant type used today, with SNRIs representing a new option. Side effects tend to be manageable, although there are concerns that antidepressants may increase suicide risk slightly. Mood stabilizers, such as lithium and valproate, are used to prevent the recurrence of episodes of disturbance in people with bipolar mood disorders.

15.15 Drug therapies can be quite effective, but they have their drawbacks. All of the drugs produce side effects, some

of which can be very troublesome. Some critics maintain that drugs' curative effects are superficial and that some drugs are overprescribed. Disturbing questions have been raised about the scientific impartiality of contemporary research on therapeutic drugs.

15.16 Electroconvulsive therapy (ECT) is used to trigger a cortical seizure that is believed to have therapeutic value for mood disorders, especially depression. Evidence about the effectiveness of ECT is contradictory but seems sufficient to justify conservative use of the procedure. Cognitive deficits are the principal risk, with much debate about how severe and enduring these deficits tend to be.

15.17 Transcranial magnetic stimulation is a new technique that permits scientists to temporarily enhance or depress activity in a specific area of the cortex. It may have value in the treatment of depression. In deep brain stimulation a thin electrode is surgically implanted so that electrical currents can be delivered to selected areas of the brain. It may have value in the treatment of depression or obsessive-compulsive disorder.

Current Trends and Issues in Treatment

The controversy about ECT is only one of many contentious issues and shifting trends in the world of mental health care. In this section, we will discuss the impact of managed care on psychotherapy, the continuing trend toward blending various approaches to therapy, and efforts to respond more effectively to increasing cultural diversity in Western societies.

Grappling with the Constraints of Managed Care

The 1990s brought a dramatic shift in how people in the United States pay for their health care. Alarmed by skyrocketing health care costs, huge numbers of employers and individuals moved from traditional fee-for-service arrangements to managed care health plans (Hogan & Morrison, 2003; Kiesler, 2000). In the *fee-for-service* system, hospitals, physicians, psychologists, and other providers charged fees for whatever health care services were needed, and most of these fees were reimbursed by private insurance or the government (through Medicaid, Medicare, and other programs). In *managed care systems* people enroll in prepaid plans with small co-payments for services, typically run by health maintenance organizations (HMOs), which agree to provide ongoing health care for a specific sum of money. Managed care usually involves a tradeoff: Consumers pay lower prices for their care, but they give up much of their freedom to choose their providers and to obtain whatever treatments they believe necessary. If an HMO's treatment expenses become excessive, it won't turn a profit, so HMOs have strong incentives to hold treatment costs down. The HMOs originally promised individuals and employers that they would be able to hold costs down without having a negative impact on the quality of care, by negotiating lower fees from providers, reducing inefficiency, and cracking down on medically unnecessary services. However, critics charge that managed care systems have squeezed all the savings they can out of the "fat" that existed in the old system and that they have responded to continued inflation in their costs by rationing care and limiting access to medically *necessary* services (Duckworth & Borus, 1999; Giles & Marafiote, 1998; Sanchez & Turner, 2003).

The possibility that managed care is having a negative effect on the quality of treatment is a source of concern throughout the health care professions, but the issue is especially sensitive in the domain of mental health care (Bursztajn & Brodsky, 2002; Campbell, 2000; Rosenberg & DeMaso, 2008). Critics maintain that mental health care has suffered particularly severe cuts in services because the question of what is "medically necessary" can be more subjective than in other treatment specialties (such as cardiology) and because patients who are denied psychotherapy services are relatively unlikely to complain (Duckworth & Borus, 1999). For example, a business executive who is trying to hide his depression or cocaine addiction from his employer will be reluctant to complain to his employer if therapeutic services are denied.

According to critics, the restriction of mental health services sometimes involves outright denial of treatment, but it often takes more subtle forms, such as underdiagnosing conditions, failing to make needed referrals to mental health specialists, and arbitrarily limiting the length of treatment (Miller, 1996). Long-term therapy is becoming a thing of the past unless patients can pay for it out of pocket, and the goal of treatment has been reduced to reestablishing a reasonable level of functioning (Zatzick, 1999). Many managed care systems hold down costs by rerouting patients from highly trained providers, such as psychiatrists and psychologists, to less-well-trained providers, such as masters-level counselors, who may not be adequately prepared to handle serious psychological disorders (Seligman & Levant, 1998). Cost containment is also achieved by requiring physicians to prescribe older antidepressant and antipsychotic drugs instead of the newer and much more expensive SSRIs and atypical antipsychotics (Docherty, 1999).

Unfortunately, there are no simple solutions to these problems on the horizon. Restraining the rapid growth of health care costs without compromising the quality of care, consumers' freedom of choice, and providers' autonomy is an enormously complex and daunting challenge. At this juncture, it is difficult to predict what the future holds. However, it is clear that economic realities have ushered in an era of transition for the treatment of psychological disorders and problems (Huey et al., 2005).

Blending Approaches to Treatment

In this chapter we have reviewed many approaches to treatment. However, there is no rule that a client
THERAPY/FOUNDER

ROOTS OF DISORDERS

PSYCHOANALYSIS

National Library of Medicine
Developed by Sigmund Freud in Vienna, from the 1890s through the 1930s

Intrapsychic conflict (among id, ego, and superego) → Anxiety → Reliance on defense mechanisms

Unconscious conflict resulting from fixations in earlier development cause anxiety, which leads to defensive behavior. The repressed conflicts typically center on sex and aggression.

CLIENT-CENTERED THERAPY

Created by Carl Rogers at the University of Chicago during the 1940s and 1950s

Courtesy of Center for Studies of the Person

Need to distort shortcomings to feel worthy of affection → Relatively incongruent self-concept → Recurrent anxiety

Defensive behavior protects inaccurate self-concept
Overdependence on acceptance from others fosters incongruence, which leads to anxiety and defensive behavior and thwarts personal growth.

BEHAVIOR THERAPY

Courtesy of Dr. Joseph Wolpe

Launched primarily by South African Joseph Wolpe's description of systematic desensitization in 1958
Maladaptive patterns of behavior are acquired through learning. For example, many phobias are thought to be created through classical conditioning and maintained by operant conditioning.

Antianxiety, antidepressant, antipsychotic, and mood-stabilizing drugs, electro-convulsive therapy

must be treated with just one approach. Often, a clinician will use several techniques in working with a client. For example, a depressed person might receive cognitive therapy, social skills training, and antidepressant medication. Multiple approaches are particularly likely when a treatment team provides therapy. Studies suggest that combining approaches to treatment has merit (Glass, 2004; Riba & Miller, 2003), as you will see in our Featured Study for this chapter.

FEATURED STUDY

Combining Insight Therapy and Medication

Depression is common in older people and contributes to physical health problems, chronic disability, and increased mortality among the elderly. Geriatric depression is also a highly recurrent problem. After successful treatment of depression, elderly patients tend to relapse more quickly and more frequently than younger clients. The purpose of this study was to determine whether a combination of insight therapy and antidepressant medication could reduce the recurrence of depression in an elderly population.

Method

Participants. The participants were 107 elderly patients diagnosed with recurrent, unipolar, major depression. The mean age of the patients at the beginning of the study was 67.6. The subjects had all been successfully treated for a recent episode of depression and had remained stable for four months.

Treatments. The medication employed in the study was *nortriptyline,* a tricyclic antidepressant that appears to be relatively effective and well tolerated in elderly populations. The insight therapy was *interpersonal psychotherapy (IPT),* an approach to therapy that emphasizes the social roots of depression and focuses on how improved social relations can protect against depression (Klerman & Weissman, 1993). Clients learn how social isolation and unsatisfying interpersonal relationships can provoke depression and how confidants and supportive interactions can decrease vulnerability to depression.

Design. The subjects were randomly assigned to one of four maintenance treatment conditions: (1) monthly interpersonal therapy and medication, (2) medication alone, (3) monthly interpersonal therapy and placebo medication, and (4) placebo medication alone. A *double-blind* procedure was employed, so the clinicians who provided the treatments did not know which subjects were getting genuine medication as opposed to placebo pills. Patients remained in maintenance treatment for three years or until a recurrence of a major depressive episode.

Results

The relapse rates for the four treatment conditions are shown in **Figure 15.16**. The relapse rate for the combination of interpersonal therapy and medication was significantly less than that for either medication alone or interpersonal therapy alone (with placebo medication). The

prophylactic value of the combined therapy proved most valuable to patients over 70 years of age and in the first year of the study, during which most relapses occurred.

Discussion

The authors conclude that "the continuation of combined medication and psychotherapy may represent the best long-term treatment strategy for preserving recovery in elderly patients with recurrent major depression" (p. 44). They speculate that the combined treatment may be "best-suited for dealing with both the biological and psychosocial substrates of old-age depression" (p. 45). How-
Figure 15.16

Relapse rates in the Reynolds et al. (1999) study. Following up over a period of three years, Reynolds et al. (1999) compared the preventive value of (1) monthly interpersonal therapy and medication, (2) medication alone, (3) monthly interpersonal therapy and placebo medication, and (4) placebo medication alone in a sample of elderly patients prone to recurrent depression. The combined treatment of insight therapy and medication yielded the lowest relapse rates and thus proved superior to either insight therapy or drug therapy alone.

ever, they acknowledge the need for further research and recommend additional studies with newer antidepressant drugs (the SSRIs) that are increasingly popular.

Comment

This study was featured because it illustrated how to conduct a well-controlled experimental evaluation of the efficacy of therapeutic interventions. It also highlighted the value of combining approaches to treatment, which is a laudable trend in the treatment of psychological disorders. The fact that the study was published in the highly prestigious *Journal of the American Medical Association* also demonstrates how prominent and important research on therapeutic efficacy has become in the era of managed care.

The value of multiple approaches to treatment may explain why a significant trend seems to have crept into the field of psychotherapy: a movement away from strong loyalty to individual schools of thought and a corresponding move toward integrating various approaches to therapy (Castonguay et al., 2003; D. A. Smith, 1999). Most clinicians used to depend exclusively on one system of therapy while rejecting the utility of all others. This era of fragmentation may be drawing to a close. One survey of psychologists' theoretical orientations, which is summarized in **Figure 15.17**, found that 36% of the respondents described themselves as *eclectic* in approach (Norcross, Hedges, & Castle, 2002).

Eclecticism **in the practice of therapy involves drawing ideas from two or more systems of therapy instead of committing to just one system.** Therapists can be eclectic in a number of ways (Arkowitz, 1992; Feixas & Botella, 2004; Goin, 2005). Two common approaches are theoretical integration and technical eclecticism. In *theoretical integration,* two or more systems of therapy are combined or blended to take advantage of the strengths of each. Paul Wachtel's (1977, 1991) efforts to blend psychodynamic and behavioral therapies is a prominent example. *Technical eclecticism* involves borrowing ideas, insights, and techniques from a variety of sources while tailoring one's intervention strategy to the unique needs of each client. Advocates of technical eclecticism, such as Arnold Lazarus (1992, 1995, 2008), maintain that therapists should ask themselves, "What is the best approach for this specific client, problem, and situation?" and then adjust their strategy accordingly.

Increasing Multicultural Sensitivity in Treatment

Modern psychotherapy emerged during the second half of the 19th century in Europe and America, spawned in part by a cultural milieu that viewed the self as an independent, reflective, rational being, capable of self-improvement (Cushman, 1992). Psy-

chological disorders were assumed to have natural causes like physical diseases and to be amenable to medical treatments derived from scientific research. But the individualized, medicalized institution of modern psychotherapy reflects Western cultural values that are far from universal (Sue & Sue, 1999). In many nonindustrialized societies, psychological disorders are attributed to supernatural forces (possession, witchcraft, angry gods, and so forth), and victims seek help from priests, shamans, and folk healers, rather than doctors (Wittkower & Warnes, 1984). Thus, efforts to export Western psychotherapies to non-Western cultures have met with mixed success. Indeed, the highly culture-bound origins of modern therapies have raised questions about their applicability to ethnic minorities *within* Western culture (Miranda et al., 2005).

Research on how cultural factors influence the process and outcome of psychotherapy has burgeoned in recent years, motivated in part by the need to improve mental health services for ethnic minority groups in American society (Lee & Ramirez, 2000; Worthington, Soth-McNett, & Moreno, 2007). The data are ambiguous for a couple of ethnic groups, but studies suggest that American minority groups generally underutilize therapeutic services (Bender
Figure 15.17
The leading approaches to therapy among psychologists. These data, from a survey of 531 psychologists who belong to the American Psychological Association's Division of Psychotherapy, provide some indication of how common an eclectic approach to therapy has become. The findings suggest that the most widely used approaches to therapy are eclectic, psychodynamic, and cognitive-behavioral treatments. (Based on data from Norcross, Hedges, & Castle, 2002)

et al., 2007; Olfson et al., 2002; Richardson, et al., 2003). Why? A variety of barriers appear to contribute to this problem (Snowden & Yamada, 2005; Zane et al., 2004; U.S. Department of Health and Human Services, 1999). One major consideration is that many members of minority groups have a history of frustrating interactions with American bureaucracies and are distrustful of large, intimidating institutions, such as hospitals and community mental health centers. Another issue is that most hospitals and mental health agencies are not adequately staffed with therapists who speak the languages used by minority groups in their service areas. Yet another problem is that the vast majority of therapists have been trained almost exclusively in the treatment of white middle-class Americans and are not familiar with the cultural backgrounds and unique characteristics of various ethnic groups. This culture gap often leads to misunderstandings and ill-advised treatment strategies.

Ethnicity aside, those who are poor are less likely than others to gain access to psychotherapy (Smith, 2005). This problem affects ethnic minorities disproportionately because many minority groups suffer from elevated rates of joblessness and poverty. And some critics argue that many middle-class therapists don't feel comfortable with impoverished clients and tend to distance themselves from the poor (Lott, 2002; Smith, 2005). Although this social class bias surely is not limited to therapists, it creates another huge barrier to equal access for those who already have to grapple with countless problems associated with poverty.

What can be done to improve mental health services for American minority groups? Researchers in this area have offered a variety of suggestions (Hong, Garcia, & Soriano, 2000; Miranda et al., 2005; Pedersen, 1994; Yamamoto et al., 1993). Discussions of possible solutions usually begin with the need to recruit and train more ethnic minority therapists. Studies show that ethnic minorities are more likely to go to mental health facilities that are staffed by a higher proportion of people who share their ethnic background (Snowden & Hu, 1996; Sue, Zane, & Young, 1994). Individual therapists have been urged to work harder at building a vigorous *therapeutic alliance* (a strong supportive bond) with their ethnic clients. A strong therapeutic alliance is associated with better therapeutic outcomes regardless of ethnicity, but some studies suggest that it is especially crucial for minority clients (Bender et al., 2007; Comas-Diaz, 2006). Finally, most authorities urge further investigation of how traditional approaches to therapy can be modified and tailored to be more compatible with specific cultural groups' attitudes, values, norms, and traditions (Hwang, 2006). A recent review of 76 studies that examined the effects of culturally adapted interventions found clear evidence that this tailoring process tends to yield positive effects (Griner & Smith, 2006). The benefits are particularly prominent when a treatment is tailored to a single, specific cultural group rather than a mixture of several or more cultural groups.

REVIEW of Key Points

15.18 In managed care systems, consumers usually pay lower prices but give up some of their freedom to obtain whatever treatments they believe necessary. Many clinicians and their clients believe that managed care has restricted access to mental health care and undermined its quality, as long-term therapy has become a thing of the past.

15.19 Combinations of insight, behavioral, and biomedical therapies are often used fruitfully in the treatment of psychological disorders. For example, the Featured Study showed how the tandem of interpersonal therapy and antidepressant medication could be valuable in preventing additional depressive episodes in an elderly population. Many modern therapists are eclectic, using specific ideas, techniques, and strategies gleaned from a number of theoretical approaches.

15.20 Because of cultural, language, and access barriers, therapeutic services are underutilized by most ethnic minorities in America. More culturally responsive approaches to treatment will require more minority therapists, more effort to build strong therapeutic alliances, and additional investigation of how traditional therapies can be tailored to be more compatible with specific ethnic groups' cultural heritage.

Institutional Treatment in Transition
Key Learning Goals

15.21 Explain why people grew disenchanted with mental hospitals.

15.22 Assess the effects of the deinstitutionalization movement.

Traditionally, much of the treatment of mental illness has been carried out in institutional settings, primarily in mental hospitals. **A *mental hospital* is a medical institution specializing in providing inpatient care for psychological disorders.** In the United States, a national network of state-funded mental hospitals started to emerge in the 1840s through the efforts of Dorothea Dix and other reformers (see **Figure 15.18**). Prior to these reforms, the mentally ill who were poor were housed in jails

Figure 15.18

Dorothea Dix and the advent of mental hospitals in America. During the 19th century, Dorothea Dix (inset) campaigned tirelessly to obtain funds for building mental hospitals. Many of these hospitals, such as the New York State Lunatic Asylum, were extremely large facilities. Although public mental hospitals improved the care of the mentally ill, they had a variety of shortcomings, which eventually prompted the deinstitutionalization movement.

SOURCE: National Library of Medicine; (inset) Detail of painting of Dorothea Dix in Harrisburg State Hospital, photo by Ken Smith/LLR Collection.

and poorhouses or were left to wander the countryside. Today, mental hospitals continue to play an important role in the delivery of mental health services. However, since World War II, institutional care for mental illness has undergone a series of major transitions—and the dust hasn't settled yet. Let's look at how institutional care has evolved in recent decades.

Disenchantment with Mental Hospitals

By the 1950s, it had become apparent that public mental hospitals were not fulfilling their goals very well (Mechanic, 1980; Menninger, 2005). Experts began to realize that hospitalization often *contributed* to the development of pathology instead of curing it. What were the causes of these unexpected negative effects? Part of the problem was that the facilities were usually underfunded (Bloom, 1984). The lack of adequate funding meant that the facilities were overcrowded and understaffed. Hospital personnel were undertrained and overworked, making them hard-pressed to deliver minimal custodial care. Despite gallant efforts at treatment, the demoralizing conditions made most public mental hospitals decidedly nontherapeutic (Scull, 1990). These problems were aggravated by the fact that state mental hospi-

tals served large geographic regions but were rarely placed near major population centers. As a result, most patients were uprooted from their community and isolated from their social support networks.

Disenchantment with the public mental hospital system inspired the *community mental health movement* that emerged in the 1960s (Duckworth & Borus, 1999; Huey, Ford, & Cole, 2005). The community mental health movement emphasizes (1) local, community-based care, (2) reduced dependence on hospitalization, and (3) the prevention of psychological disorders. Community mental health centers were intended to supplement mental hospitals with decentralized and more accessible services, but they have had their own funding struggles (Dixon & Goldman, 2004).

Deinstitutionalization

Mental hospitals continue to care for many people troubled by chronic mental illness, but their role in patient care has diminished. Since the 1960s, a policy of deinstitutionalization has been followed in the United States, as well as most other Western countries (Fakhoury & Priebe, 2002). *Deinstitutionalization* **refers to transferring the treatment of mental illness from inpatient institutions to community-based facilities that emphasize outpatient**

care. This shift in responsibility was made possible by two developments: (1) the emergence of effective drug therapies for severe disorders and (2) the deployment of community mental health centers to coordinate local care (Goff & Gudeman, 1999).

The exodus of patients from mental hospitals has been dramatic. The average inpatient population in state and county mental hospitals had dropped from a peak of nearly 550,000 in the mid-1950s to around 70,000 by 2000, as shown in **Figure 15.19**. This trend does not mean that hospitalization for mental illness has become a thing of the past. A great many people are still hospitalized, but the shift has been toward placing them in local general hospitals for brief periods instead of distant psychiatric hospitals for long periods (Kiesler, 1992). In keeping with the philosophy of deinstitutionalization, these local facilities try to get patients stabilized and back into the community as swiftly as possible.

How has deinstitutionalization worked out? It gets mixed reviews. On the positive side, many people have benefited by avoiding disruptive and unnecessary hospitalization. Ample evidence suggests that alternatives to hospitalization can be as effective as and less costly than inpatient care (McGrew et al., 1999; Reinharz, Lesage, & Contandriopoulos, 2000). Moreover, follow-up studies of discharged patients reveal that a substantial majority prefer the greater freedom provided by community-based treatment (Leff, 2006).

Nonetheless, some unanticipated problems have arisen (Elpers, 2000; Munk-Jorgensen, 1999; Talbott, 2004). Many patients suffering from chronic psychological disorders had nowhere to go when they were released. They had no families, friends, or homes to return to. Many had no work skills and were poorly prepared to live on their own. These people were supposed to be absorbed by "halfway houses," sheltered workshops, and other types of intermediate care facilities. Unfortunately, many communities
Figure 15.19

Declining inpatient population at state and county mental hospitals. The inpatient population in public mental hospitals has declined dramatically since the late 1950s, as a result of deinstitutionalization and the development of effective antipsychotic medication. (Data from the National Institute of Mental Health)

were never able to fund and build the planned facilities (Hogan & Morrison, 2003; Lamb, 1998). Thus, deinstitutionalization left two major problems in its wake: a "revolving door" population of people who flow in and out of psychiatric facilities, and a sizable population of homeless mentally ill people.

Mental Illness, the Revolving Door, and Homelessness

Although the proportion of hospital days attributable to mental illness has dwindled, admission rates for psychiatric hospitals have actually climbed. What has happened? Deinstitutionalization and drug therapy have created a revolving door through which many mentally ill people pass again and again (Castro et al., 2007; Geller, 1992; Langdon et al., 2001).

DOONESBURY
Most of the people caught in the mental health system's revolving door suffer from chronic, severe disorders (usually schizophrenia) that often require hospitalization (Haywood et al., 1995). However, they respond to drug therapies in the hospital. Once they're stabilized through drug therapy, they no longer qualify for expensive hospital treatment according to the new standards created by deinstitutionalization and managed care. Thus, they're sent back out the door, into communities that often aren't prepared to provide adequate outpatient care. Because they lack appropriate care and support, their condition deteriorates and they soon require readmission to a hospital, where the cycle begins once again. Over two-thirds of all psychiatric inpatient admissions involve rehospitalizing a former patient. Moreover, 40% to 50% of patients are readmitted within a year of their release (Bridge & Barbe, 2004).

Deinstitutionalization has also been blamed for the growing population of homeless people. Studies have consistently found elevated rates of mental illness among the homeless. Taken as a whole, the evidence suggests that roughly one-third of homeless people suffer from severe mental illness (schizophrenic and mood disorders), that another one-third or more are struggling with alcohol and drug problems, that many qualify for multiple diagnoses, and that the prevalence of mental illness among the homeless may be increasing (Bassuk et al., 1998; Folsom et al., 2005; Haugland et al., 1997; North et al., 2004). In essence, homeless shelters have become a *de facto* element of America's mental health care system (Callicutt, 2006).

The popular media routinely equate homelessness with mental illness, and it is widely assumed that deinstitutionalization is largely responsible for the rapid growth of homelessness in America. Although deinstitutionalization has probably *contributed* to the growth of homelessness, many experts in this area maintain that it is an oversimplification to blame the problem of homelessness chiefly on deinstitutionalization (Main, 1998; Sullivan, Burnam, & Koegel, 2000).

In light of the revolving door problem and homelessness among the mentally ill, what can we conclude about deinstitutionalization? It appears to be a worthwhile idea that has been poorly executed (Lamb, 1998). Overall, the policy has probably been a benefit to countless people with milder disorders but a cruel trick on many others with severe, chronic disorders. Ultimately, it's clear that our society is not providing adequate care for a sizable segment of the mentally ill population (Appelbaum, 2002; Elpers, 2000; Gittelman, 2005; Torrey, 1996). That's not a new development. Inadequate care for mental illness has always been the norm. Societies always struggle with the problem of what to do with the mentally ill and how to pay for their care (Duckworth & Borus, 1999).

REVIEW of Key Points

15.21 Experts eventually realized that mental hospitals often contributed to the development of pathology instead of curing it, in part because they tended to be underfunded and understaffed, leading to demoralizing conditions. Disenchantment with the negative effects of mental hospitals led to the advent of more localized community mental health centers and a policy of deinstitutionalization.

15.22 As a result of deinstitutionalization, long-term hospitalization for mental disorders is largely a thing of the past. Deinstitutionalization has worked well for some patients, but it has spawned some unanticipated problems, including the revolving door problem and increased homelessness.

Reflecting on the Chapter's Themes

In our discussion of psychotherapy, one of our unifying themes—the value of theoretical diversity—was particularly prominent, and one other theme—the importance of culture—surfaced briefly. Let's discuss the latter theme first. The approaches to treatment described in this chapter are products of modern, white, middle-class, Western culture. Some of these therapies have proven useful in some other cultures, but many have turned out to be irrelevant or counterproductive when used with different cultural groups, including ethnic minorities in Western society. Thus, we have seen once again that cultural factors influence psychological processes and that Western psychology cannot assume that its theories and practices have universal applicability.

As for theoretical diversity, its value can be illustrated with a rhetorical question: Can you imagine what the state of modern psychotherapy would be if everyone in psychology and psychiatry had simply accepted Freud's theories about the nature and
Key Learning Goals

15.23 Identify the two unifying themes highlighted in this chapter.

Cultural Heritage

Theoretical Diversity

treatment of psychological disorders? If not for theoretical diversity, psychotherapy might still be in the dark ages. Psychoanalysis can be a useful method of therapy, but it would be a tragic state of affairs if that were the *only* treatment available. Multitudes of people have benefited from alternative approaches to treatment that emerged out of tensions between psychoanalytic theory and other theoretical perspectives. People have diverse problems, rooted in varied origins, that call for the pursuit of different therapeutic goals. Thus, it's fortunate that people can choose from a diverse array of approaches to treatment. The illustrated overview on pages 646–647 summarizes and compares some of the approaches that we've discussed in this chapter. This summary chart shows that the major approaches to treatment

each have their own vision of the nature of human discontent and the ideal remedy.

Of course, diversity can be confusing. The range and variety of available treatments in modern psychotherapy leaves many people puzzled about their options. Thus, in the Personal Application we'll sort through the practical issues involved in selecting a therapist.

REVIEW of Key Points

15.23 Our discussion of psychotherapy highlighted the value of theoretical diversity. Conflicting theoretical orientations have generated varied approaches to treatment. Our coverage of therapy also showed once again that cultural factors shape psychological processes.

PERSONAL

APPLICATION

Looking for a Therapist

Key Learning Goals

15.24 Discuss where to seek therapy and the potential importance of a therapist's sex and professional background.

15.25 Evaluate the importance of a therapist's theoretical approach.

15.26 Summarize what one should look for in a prospective therapist and what one should expect out of therapy.

Answer the following "true" or "false."

____ **1** Psychotherapy is an art as well as a science.

____ **2** Psychotherapy can be harmful or damaging to a client.

____ **3** Psychotherapy does not have to be expensive.

____ **4** The type of professional degree that a therapist holds is relatively unimportant.

All of these statements are true. Do any of them surprise you? If so, you're in good company. Many people know relatively little about the practicalities of selecting a therapist.

The task of finding an appropriate therapist is complex. Should you see a psychologist or psychiatrist? Should you opt for indi-

vidual therapy or group therapy? Should you see a client-centered therapist or a behavior therapist? The unfortunate part of this situation is that people seeking psychotherapy often feel overwhelmed by personal difficulties. The last thing they need is to be confronted by yet another complex problem.

Nonetheless, the importance of finding a good therapist cannot be overestimated. Treatment can sometimes have harmful rather than helpful effects. We have already discussed how drug therapies and ECT can sometimes be damaging, but problems are not limited to these interventions. Talking about your problems with a therapist may sound harmless, but studies indicate that insight therapies can also backfire (Lambert & Ogles, 2004; Lilienfeld, 2007). Although a great many talented therapists are available, psychotherapy, like any other profession, has incompetent practitioners as well. Therefore, you should shop for a skilled therapist, just as you would for a good attorney or a good mechanic.

In this application, we'll go over some information that should be helpful if you ever have to look for a therapist for yourself or for a friend or family member (based on

Beutler, Bongar, & Shurkin, 2001; Ehrenberg & Ehrenberg, 1994; Pittman, 1994).

Where Do You Find Therapeutic Services?

Psychotherapy can be found in a variety of settings. Contrary to general belief, most therapists are not in private practice. Many work in institutional settings such as community mental health centers, hospitals, and human service agencies. The principal sources of therapeutic services are described in Table 15.2. The exact configuration of therapeutic services available will vary from one community to another. To find out what your community has to offer, it is a good idea to consult your friends, your local phone book, or your local community mental health center.

Is the Therapist's Profession or Sex Important?

Psychotherapists may be trained in psychology, psychiatry, social work, counseling, psychiatric nursing, or marriage and family therapy. Researchers have *not* found any re-
Finding the right therapist is no easy task. You need to take into account the therapist's training and orientation, fees charged, and personality. An initial visit should give you a good idea of what a particular therapist is like.

liable associations between therapists' professional background and therapeutic efficacy (Beutler et al., 2004), probably because many talented therapists can be found in all of these professions. Thus, the kind of degree that a therapist holds doesn't need to be a crucial consideration in your selection process.

Whether a therapist's sex is important depends on your attitude (Nadelson, Notman, & McCarthy, 2005). If *you* feel that the therapist's sex is important, then for you it is. The therapeutic relationship must be characterized by trust and rapport. Feeling uncomfortable with a therapist of one sex or the other could inhibit the therapeu-

tic process. Thus, you should feel free to look for a male or female therapist if you prefer to do so. This point is probably most relevant to female clients whose troubles may be related to sexism in our society (Kaplan, 1985). It is entirely reasonable for women to seek a therapist with a feminist perspective if that would make them feel more comfortable.

Speaking of sex, you should be aware that sexual exploitation is an occasional problem in the context of therapy. Studies indicate that a small minority of therapists take advantage of their clients sexually (Pope, Keith-Spiegel, & Tabachnick, 1986). These incidents almost always involve a male therapist making advances to a female client. The available evidence indicates that these sexual liaisons are usually harmful to clients (Gabbard, 1994; Williams, 1992). There are absolutely no situations in which therapist-client sexual relations are an ethical therapeutic practice. If a therapist makes sexual advances, a client should terminate treatment.

Is Treatment Always Expensive?

Psychotherapy does not have to be prohibitively expensive. Private practitioners tend to be the most expensive, charging between $75 and $140 per (50-minute) hour. These fees may seem high, but they are in line with those of similar professionals, such as dentists and attorneys. Community mental health centers and social service agencies are usually supported by tax dollars. As a result they can charge lower fees than most therapists in private practice. Many of these organizations use a sliding scale, so that clients are charged according to how much they can afford to pay. Thus, most communities have inexpensive opportunities for psychotherapy. Moreover, most health insurance plans and HMOs provide coverage for at least some forms of mental health care.

Is the Therapist's Theoretical Approach Important?

Logically, you might expect that the diverse approaches to therapy ought to vary

Table 15.2 Principal Sources of Therapeutic Services

Source	Comments
Private practitioners	Self-employed therapists are listed in the Yellow Pages under their professional category, such as psychologists or psychiatrists. Private practitioners tend to be relatively expensive, but they also tend to be highly experienced therapists.
Community mental health centers	Community mental health centers have salaried psychologists, psychiatrists, and social workers on staff. The centers provide a variety of services and often have staff available on weekends and at night to deal with emergencies.
Hospitals	Several kinds of hospitals provide therapeutic services. There are both public and private mental hospitals that specialize in the care of people with psychological disorders. Many general hospitals have a psychiatric ward, and those that do not usually have psychiatrists and psychologists on staff and on call. Although hospitals tend to concentrate on inpatient treatment, many provide outpatient therapy as well.
Human service agencies	Various social service agencies employ therapists to provide short-term counseling. Depending on your community, you may find agencies that deal with family problems, juvenile problems, drug problems, and so forth.
Schools and workplaces	Most high schools and colleges have counseling centers where students can get help with personal problems. Similarly, some large businesses offer in-house counseling to their employees.

in their effectiveness. For the most part, this is *not* what researchers find, however. After reviewing many studies of therapeutic efficacy, Jerome Frank (1961) and Lester Luborsky and his colleagues (1975) both quote the dodo bird who has just judged a race in *Alice in Wonderland:* "*Everybody* has won, and *all* must have prizes." Improvement rates for various theoretical orientations usually come out pretty close in most studies (Lambert & Bergin, 2004; Luborsky et al., 2002; Wampold, 2001; see **Figure 15.20**).

However, these findings are a little misleading, as the estimates of overall effectiveness have been averaged across many types of patients and many types of problems. Most experts seem to think that *for certain types of problems, some approaches to therapy are more effective than others* (Beutler, 2002; Crits-Christoph, 1997; Norcross, 1995). For example, Martin Seligman (1995) asserts that panic disorders respond best to cognitive therapy, that specific phobias are most amenable to treatment with systematic desensitization, and that obsessive-compulsive disorders are best treated with behavior therapy or medication. Thus, for a specific type of problem, a therapist's theoretical approach *may* make a difference.

It is also important to point out that the finding that different approaches to therapy are roughly equal in overall efficacy does not mean that all *therapists* are created equal. Some therapists unquestionably

Therapy is both a science and an art. It is scientific in that practitioners are guided in their work by a huge body of empirical research. It is an art in that therapists often have to be creative in adapting their treatment procedures to individual patients and their idiosyncrasies.

are more effective than others. However, these variations in effectiveness appear to depend on individual therapists' personal skills rather than on their theoretical orientation (Beutler et al., 2004). Good, bad, and mediocre therapists are found within each school of thought.

The key point is that effective therapy requires skill and creativity. Arnold Lazarus, who devised multimodal therapy, emphasizes that therapists "straddle the fence between science and art." Therapy is scientific in that interventions are based on extensive theory and empirical research (Forsyth & Strong, 1986). Ultimately, though, each client is a unique human being, and the therapist has to creatively fashion a treatment program that will help that individual.

Figure 15.20

Estimates of the effectiveness of various approaches to psychotherapy. Smith and Glass (1977) reviewed nearly 400 studies in which clients who were treated with a specific type of therapy were compared with a control group made up of individuals with similar problems who went untreated. The bars indicate the percentile rank (on outcome measures) attained by the average client treated with each type of therapy when compared to control subjects. The higher the percentile, the more effective the therapy was. As you can see, the various approaches were fairly similar in their overall effectiveness.

SOURCE: Adapted from Smith, M. L., & Glass, G. V. (1977). Meta-analysis of psychotherapy outcome series. *American Psychologist, 32,* 752–760. Copyright © 1977 by the American Psychological Association. Adapted by permission of the author.
What Should You Look For in a Prospective Therapist?

Some clients are timid about asking prospective therapists questions about their training, approach, fees, and so forth. However, these are reasonable questions, and the vast majority of therapists will be most accommodating in providing answers. Usually, you can ask your preliminary questions over the phone. If things seem promising, you may decide to make an appointment for an interview (for which you will probably have to pay). In this interview, the therapist will gather more information to determine the likelihood of helping you, given his or her training and approach to treatment. At the same time, you should be making a similar judgment about whether *you* believe the therapist can help you with your problems.

What should you look for? First, you should look for personal warmth and sincere concern. Try to judge whether you will be able to talk to this person in a candid, nondefensive way. Second, look for empathy and understanding. Is the person capable of appreciating your point of view? Third, look for self-confidence. Self-assured therapists will communicate a sense of competence without trying to intimidate you with jargon or boasting needlessly about what they can do for you. When all is said and done, you should *like* your therapist. Otherwise, it will be difficult to establish the needed rapport.

What Is Therapy Like?

It is important to have realistic expectations about therapy, or you may be unnecessarily disappointed. Some people expect miracles. They expect to turn their life around quickly with little effort. Others expect their therapist to run their lives for them. These are unrealistic expectations.

Therapy is usually a slow process. Your problems are not likely to melt away quickly. Moreover, therapy is hard work, and your therapist is only a facilitator. Ultimately, *you* have to confront the challenge of changing your behavior, your feelings, or your personality. This process may not be pleasant. You may have to face up to some painful truths about yourself. As Ehrenberg and Ehrenberg (1986) point out, "Psychotherapy takes time, effort, and courage."

REVIEW of Key Points

15.24 Therapeutic services are available in many settings, and such services need not be expensive. Both excellent and mediocre therapists can be found in all of the mental health professions. Thus, therapists' personal skills are more important than their professional degree. Whether a therapist's sex is important depends on the client's attitude.

15.25 The various theoretical approaches to therapy appear to be fairly similar in overall effectiveness. However, for certain types of problems, some approaches are probably more effective than others, and all therapists are not created equal.

15.26 In selecting a therapist, warmth, empathy, confidence, and likability are desirable traits. It is important to have realistic expectations about therapy. Therapy tends to be a slow, challenging process requiring hard work.

Key Learning Goals

15.27 Understand how placebo effects and regression toward the mean can complicate the evaluation of therapy.

From Crisis to Wellness—But Was It the Therapy?

It often happens this way. Problems seem to go from bad to worse—the trigger could be severe pressures at work, an acrimonious fight with your spouse, or a child's unruly behavior spiraling out of control. At some point, you recognize that it might be prudent to seek professional assistance from a therapist, but where do you turn? If you are like most people, you will probably hesitate before actively seeking professional help. People hesitate because therapy carries a stigma, because the task of finding a therapist is daunting, and because they hope that their psychological problems will clear up on their own—which *does* happen with some regularity. When people finally decide to pursue mental health care, it is often because they feel like they have reached rock bottom in terms of their functioning and they have no choice. Motivated by their crisis, they enter into treatment, looking for a ray of hope. Will therapy help them feel better?

It may surprise you to learn that the answer *generally* would be "yes," even if professional treatment itself were utterly worthless and totally ineffectual. There are two major reasons that people entering therapy are likely to get better, regardless of whether their treatment is effective. You can probably guess one of these reasons, which has been mentioned repeatedly in the chapter: the power of the *placebo*. **Placebo effects occur when people's expectations lead them to experience some change even though they receive a fake treatment** (like getting a sugar pill instead of a real drug). Clients generally enter therapy with expectations that it will have positive effects, and as we have emphasized throughout this text, *people have a remarkable tendency to see what they expect to see.* Because of this factor, studies of the efficacy of medical drugs always include a placebo condition in which subjects are given fake medication (see Chapter 2). Researchers are often quite surprised

by just how much the placebo subjects improve (Fisher & Greenberg, 1997; Walsh et al., 2002). Placebo effects can be powerful and should be taken into consideration whenever efforts are made to evaluate the efficacy of some approach to treatment.

The other factor at work is the main focus in this Application. It is an interesting statistical phenomenon that we have not discussed previously: *regression toward the mean.* **Regression toward the mean occurs when people who score extremely high or low on some trait are measured a second time and their new scores fall closer to the mean (average).** Regression effects work in both directions: On the second measurement high scorers tend to fall back toward the mean and low scorers tend to creep upward toward the mean. For example, let's say we wanted to evaluate the effectiveness of a one-day coaching program intended to improve performance on the SAT test. We reason that coaching is most likely to help students who have performed poorly on the test, so we recruit a sample of high school students who have previously scored in the bottom 20% on the SAT. Thanks to regression toward the mean, most of these students will score higher if they take the SAT a second time, so our coaching program may *look* effective even if it has no value. By the way, if we set out to see whether our coaching program could increase the performance of high scorers, regression effects would be working *against* us. If we recruited a sample of students who had scored in the upper 20% on the SAT, their scores would

tend to move downward when tested a second time, which could cancel out most or all of the beneficial effects of the coaching program. The processes underlying regression toward the mean are complex matters of probability, but they can be approximated by a simple principle: If you are near the bottom, there's almost nowhere to go but up, and if you are near the top, there's almost nowhere to go but down.

What does all of this have to do with the effects of professional treatment for psychological problems and disorders? Well, chance variations in the ups and downs of life occur for all of us. But recall that most people enter psychotherapy during a time of severe crisis, when they are at a really low point in their lives. If you measure the

Placebo effects and regression toward the mean are two prominent factors that make it difficult to evaluate the efficacy of various approaches to therapy.

mental health of a group of people entering therapy, they will mostly get relatively low scores. If you measure their mental health again a few months later, chances are that most of them will score higher—with or without therapy—because of regression toward the mean. This is not a matter of idle speculation. Studies of untreated subjects demonstrate that poor scores on measures of mental health regress toward the mean when participants are assessed a second time (Flett, Vredenburg, & Krames, 1995; Hsu, 1995).

Does the fact that most people will get better even without therapy mean that there is no sound evidence that psychotherapy works? No, regression effects, along with placebo effects, do create major headaches for researchers evaluating the efficacy of various therapies, but these problems *can* be circumvented. Control groups, random assignment, placebo conditions, and statistical adjustments can be used to control for regression and placebo effects, as well as for other threats to validity. As discussed in the main body of the chapter, researchers have accumulated rigorous evidence that most approaches to therapy have demonstrated efficacy. However, our discussion of placebo and regression effects shows you some of the factors that make this type of research far more complicated and challenging than might be anticipated.

Recognizing how regression toward the mean can occur in a variety of contexts is an important critical thinking skill, so let's look at some additional examples. Think about an outstanding young pro baseball player who has a fabulous first season and is named "Rookie of the Year." What sort of performance would you predict for this athlete for the next year? Before you make

Placebo effects and regression toward the mean can help explain why phony, worthless treatments can have sincere supporters who really believe that the bogus interventions are effective.

your prediction, think about regression toward the mean. Statistically speaking, our Rookie of the Year is likely to perform well above average the next year, but not as well as he did in his first year. If you are a sports fan, you may recognize this pattern as the "sophomore slump." Many sports columnists have written about the sophomore slump, which they typically blame on the athlete's personality or motivation ("He got lazy,'" "He got cocky," "The money and fame went to his head," and so forth). A simple appeal to regression toward the mean could explain this sort of outcome, with no need to denigrate the personality or motivation of the athlete. Of course, sometimes the Rookie of the

Year performs even better during his second year. Thus, our baseball example can be used to emphasize an important point. Regression toward the mean is not an inevitability. It is a statistical tendency that predicts what will happen far more often than not, but it is merely a matter of probability—which means it is a much more reliable principle when applied to groups (say, the top ten rookies in a specific year) rather than to individuals.

Let's return to the world of therapy for one last thought about the significance of both regression and placebo effects. Over the years, a host of quacks, charlatans, con artists, herbalists, and faith healers have marketed and sold an endless array of worthless treatments for both psychological problems and physical maladies. In many instances, people who have been treated with these phony therapies have expressed satisfaction or even praise and gratitude. For instance, you may have heard someone sincerely rave about some herbal remedy or psychic advice that you were pretty sure was really worthless. If so, you were probably puzzled by their glowing testimonials. Well, you now have two highly plausible explanations for why people can honestly believe that they have derived great benefit from harebrained, bogus treatments: placebo effects and regression effects. The people who provide testimonials for worthless treatments may have experienced *genuine* improvements in their conditions, but those improvements were probably the result of placebo effects and regression toward the mean. Placebo and regression effects add to the many reasons that you should always be skeptical about anecdotal evidence. And they help explain why charlatans can be so successful and why unsound, ineffective treatments can have sincere proponents.

Table 15.3 Critical Thinking Skills Discussed in This Application

Skill	Description
Recognizing situations in which placebo effects might occur	The critical thinker understands that if people have expectations that a treatment will produce a certain effect, they may experience that effect even if the treatment was fake or ineffectual.
Recognizing situations in which regression toward the mean may occur	The critical thinker understands that when people are selected for their extremely high or low scores on some trait, their subsequent scores will probably fall closer to the mean.
Recognizing the limitations of anecdotal evidence	The critical thinker is wary of anecdotal evidence, which consists of personal stories used to support one's assertions. Anecdotal evidence tends to be unrepresentative, inaccurate, and unreliable.

REVIEW of Key Points

15.27 People entering therapy are likely to get better even if their treatment is ineffective, because of placebo effects and regression toward the mean. Regression toward the mean occurs when people selected for their extremely high or low scores on some trait are measured a second time and their new scores fall closer to the mean. Regression and placebo effects may also help explain why people can often be deceived by phony, ineffectual treatments.

Key Ideas

The Elements of the Treatment Process

❚ Approaches to treatment are diverse, but they can be grouped into three categories: insight therapies, behavior therapies, and biomedical therapies.

❚ Therapists come from a variety of professional backgrounds. Clinical and counseling psychologists, psychiatrists, clinical social workers, psychiatric nurses, counselors, and marriage and family therapists are key providers of therapeutic services.

Insight Therapies

❚ Insight therapies involve verbal interactions intended to enhance self-knowledge. In psychoanalysis, free association and dream analysis are used to explore the unconscious. When an analyst's probing hits sensitive areas, resistance can be expected.

❚ The transference relationship may be used to overcome this resistance so that the client can handle interpretations that lead to insight. Classical psychoanalysis is not widely practiced anymore, but Freud's legacy lives on in a rich diversity of modern psychodynamic therapies.

❚ The client-centered therapist tries to provide a supportive climate in which clients can restructure their self-concept. The process of therapy emphasizes clarification of the client's feelings and self-acceptance. Positive psychotherapy attempts to get clients to recognize their strengths, appreciate their blessings, savor positive experiences, and to find meaning in their lives.

❚ Most theoretical approaches to insight therapy have been adapted for use with groups. Evaluating the effectiveness of any approach to treatment is complex and difficult. Nonetheless, the weight of the evidence suggests that insight therapies are superior to no treatment or placebo treatment. Studies suggest that common factors make a significant contribution to the benefits of various therapies.

Behavior Therapies

❚ Behavior therapies use the principles of learning in direct efforts to change specific aspects of behavior. Wolpe's systematic desensitization is a counterconditioning treatment for phobias. In aversion therapy, a stimulus associated with an unwanted response is paired with an unpleasant stimulus in an effort to eliminate the maladaptive response.

❚ Social skills training can improve clients' interpersonal skills through shaping, modeling, and behavioral rehearsal. Beck's cognitive therapy concentrates on changing the way clients think about events in their lives. There is ample evidence that behavior therapies are effective in the treatment of a wide variety of disorders.

Biomedical Therapies

❚ Biomedical therapies are physiological interventions for psychological problems. Antianxiety drugs are used to relieve excessive apprehension. Antipsychotic drugs are used primarily in the treatment of schizophrenia. Antidepressants are used to bring people out of episodes of depression. Bipolar mood disorders are treated with lithium and other mood stabilizers.

❚ Drug therapies can be quite effective, but they have their drawbacks. All of the drugs produce problematic side effects. The adverse effects of psychiatric drugs may be underestimated because pharmaceutical research is not as impartial as it should be.

❚ Electroconvulsive therapy (ECT) is used to trigger a cortical seizure that is believed to have therapeutic value for mood disorders, especially depression. Evidence about the effectiveness and risks of ECT is contradictory. Transcranial magnetic stimulation may have value in the treatment of depression, and deep brain stimulation is being investigated as a treatment for depression and obsessive-compulsive disorder.

Current Trends and Issues in Treatment

❚ Many clinicians and their clients believe that managed care has restricted access to mental health care and undermined its quality. Combinations of insight, behavioral, and biomedical therapies are often used fruitfully in the treatment of psychological disorders. Many modern therapists are eclectic, using specific ideas, techniques, and strategies gleaned from a number of theoretical approaches.

❚ Because of cultural, language, and access barriers, therapeutic services are underutilized by ethnic minorities in America. However, the crux of the problem is the failure of institutions to provide culturally sensitive and responsive forms of treatment for ethnic minorities.

Institutional Treatment in Transition

❚ Disenchantment with the negative effects of mental hospitals led to the advent of more localized community mental health centers and a policy of deinstitutionalization. Long-term hospitalization for mental disorders is largely a thing of the past.

❚ Unfortunately, deinstitutionalization has left some unanticipated problems in its wake, such as the revolving door problem and increased homelessness. However, many theorists believe that homelessness is primarily an economic problem.

Reflecting on the Chapter's Themes

❚ Our discussion of psychotherapy highlighted the value of theoretical diversity. Conflicting theoretical orientations have generated varied approaches to treatment. Our coverage of therapy also showed once again that cultural factors shape psychological processes.

PERSONAL APPLICATION Looking for a Therapist

❚ Therapeutic services are available in many settings, and such services need not be expensive. Excellent therapists and mediocre therapists can be found in all of the mental health professions, using the full range of therapeutic approaches.

❚ In selecting a therapist, you should look for warmth, empathy, confidence, and likability, and it is reasonable to insist on a therapist of one sex or the other. Therapy is often a difficult, gradual process that usually requires hard work.

CRITICAL THINKING APPLICATION From Crisis to Wellness—But Was It the Therapy?

❚ People entering therapy are likely to get better even if their treatment is ineffective, because of placebo effects and regression toward the mean.

❚ Regression toward the mean occurs when people selected for their extremely high or low scores on some trait are measured a second time and their new scores fall closer to the mean. Regression and placebo effects may also help explain why people can often be deceived by phony, ineffectual treatments.

Carl Rogers (pp. 628–630)
Joseph Wolpe (pp. 634–635)

1. After undergoing psychoanalysis for several months, Karen has suddenly started "forgetting" to attend her therapy sessions. Karen's behavior is most likely a form of:
   A. resistance.
   B. transference.
   C. insight.
   D. catharsis.

2. Because Suzanne has an unconscious sexual attraction to her father, she behaves seductively toward her therapist. Suzanne's behavior is most likely a form of:
   A. resistance.
   B. transference.
   C. misinterpretation.
   D. an unconscious defense mechanism.

3. The key task of the client-centered therapist is:
   A. interpretation of the client's thoughts, feelings, memories, and behaviors.
   B. clarification of the client's feelings.
   C. confrontation of the client's irrational thoughts.
   D. modification of the client's problematic behaviors.

4. The goal of behavior therapy is to:
   A. identify the early childhood unconscious conflicts that are the source of the client's symptoms.
   B. achieve major personality reconstruction.
   C. alter the frequency of specific problematic responses by using conditioning techniques.
   D. alter the client's brain chemistry by prescribing specific drugs.

5. A therapist openly challenges a client's statement that she is a failure as a woman because her boyfriend left her, insisting that she justify it with evidence. Which type of therapy is probably being used?
   A. psychodynamic therapy
   B. client-centered therapy
   C. behavior therapy
   D. cognitive therapy

6. Collectively, numerous studies of therapeutic outcome suggest that:
   A. insight therapy is superior to no treatment or placebo treatment.
   B. individual insight therapy is effective, but group therapy is not.
   C. group therapy is effective, but individual insight therapy is not.
   D. insight therapy is only effective if patients are in therapy for at least two years.

7. Systematic desensitization is particularly effective for the treatment of _____ disorders.
   A. generalized anxiety
   B. panic
   C. obsessive-compulsive
   D. phobic

8. Linda's therapist has her practice active listening skills in structured role-playing exercises. Later, Linda is gradually asked to practice these skills with family members, friends, and finally, her boss. Linda is undergoing:
   A. systematic desensitization.
   B. biofeedback.
   C. a token economy procedure.
   D. social skills training.

9. After being released from a hospital, many schizophrenic patients stop taking their antipsychotic medication because:
   A. their mental impairment causes them to forget.
   B. of the unpleasant side effects.
   C. most schizophrenics don't believe they are ill.
   D. of all of the above.

10. Selective serotonin reuptake inhibitors (SSRIs) can be effective in the treatment of _____ disorders.
    A. depressive
    B. schizophrenic
    C. obsessive-compulsive
    D. both a and c

11. Modern psychotherapy:
    A. was spawned by a cultural milieu that viewed the self as an independent, rational being.
    B. embraces universal cultural values.
    C. has been successfully exported to many non-Western cultures.
    D. involves both b and c.

12. The community mental health movement emphasizes:
    A. segregation of the mentally ill from the general population.
    B. increased dependence on long-term inpatient care.
    C. local care and the prevention of psychological disorders.
    D. all of the above.

13. Many people repeatedly go in and out of mental hospitals. Typically, such people are released because _____ ; they are eventually readmitted because _____ .
    A. they have been stabilized through drug therapy; their condition deteriorates once again because of inadequate outpatient care
    B. they run out of funds to pay for hospitalization; they once again can afford it
    C. they have been cured of their disorder; they develop another disorder
    D. they no longer want to be hospitalized; they voluntarily recommit themselves

14. The type of professional training a therapist has:
    A. is the most important indicator of his or her competence.
    B. should be the major consideration in choosing a therapist.
    C. is not all that important, since talented therapists can be found in all of the mental health professions.
    D. involves both a and b.

15. Which of the following could be explained by regression toward the mean?
    A. You get an average bowling score in one game and a superb score in the next game.
    B. You get an average bowling score in one game and a very low score in the next game.
    C. You get an average bowling score in one game and another average score in the next game.
    D. You get a terrible bowling score in one game and an average score in the next game.

SOCIAL BEHAVIOR

© Jose Fuste Raga/Corbis

Text not available due to copyright restrictions

The preceding account is a real story, taken from a book about contemporary intimate relationships (Lavin & Kavesh, 1988, pp. 118–121). Muffy is on the horns of a difficult dilemma. Romantic relationships are important to most people, but so are friendships, and Muffy may have to choose between the two. Muffy's story illustrates the significance of social relations in people's lives. It also foreshadows each of the topics that we'll cover in this chapter, as we look at behavior in its social context.

Social psychology is the branch of psychology concerned with the way individuals' thoughts, feelings, and behaviors are influenced by others. Our coverage of social psychology will focus on six broad topics highlighted in Muffy's story:

• *Person perception.* The crux of Muffy's problem is that Jake didn't make a very good impression on her friends, primarily because her friends have preconceived views of "working-class stiffs." To what extent do people's expectations color their impressions of others?

• *Attribution processes.* Muffy is struggling to understand her friends' rejection of Jake. When she implies that it is due to their snotty elitism, she's engaging in attribution, making an inference about the causes of her friends' behavior. How do people use attributions to explain social behavior?

• *Interpersonal attraction.* Jake and Muffy are different in many important ways—is it true that opposites attract? Why does Jake's lack of similarity to Muffy's friends lead to such disdain?

• *Attitudes.* Muffy's girlfriends have negative attitudes about working-class men. How are attitudes formed? What leads to attitude change? How do attitudes affect people's behavior?

• *Conformity and obedience.* Muffy's friends discourage her from dating Jake, putting her under pressure to conform to their values. What factors influence conformity? Can people be coaxed into doing things that contradict their values?

• *Behavior in groups.* Muffy belongs to a tight-knit group of friends who think along similar lines. Do people behave differently when they are in groups as opposed to when they are alone? Why do people in groups often think alike?

Social psychologists study how people are affected by the actual, imagined, or implied presence of others. Their interest is not limited to individuals' interactions with others, as people can engage in social behavior even when they're alone. For instance, if you were driving by yourself on a deserted highway and tossed your trash out your car window, your littering would be a social action. It would defy social norms, reflect your socialization and attitudes, and have repercussions (albeit, small) for other people in your society. Social psychologists often study individual behavior in a social context. This interest in understanding individual behavior should be readily apparent in our first section, on person perception.

Person Perception: Forming Impressions of Others

Key Learning Goals

16.1 Understand how aspects of physical appearance may influence impressions of others.

16.2 Clarify how stereotyping and other factors contribute to subjectivity in person perception.

16.3 Articulate the evolutionary perspective on bias in person perception.

Can you remember the first meeting of your introductory psychology class? What impression did your professor make on you that day? Did your instructor appear to be confident? Easygoing? Pompous? Open-minded? Cynical? Friendly? Were your first impressions supported or undermined by subsequent observations? When you interact with people, you're constantly engaged in *person perception,* **the process of forming impressions of others.** People show considerable ingenuity in piecing together clues about others' characteristics. However, impressions are often inaccurate because of the many biases and fallacies that occur in person perception. In this section we consider some of the factors that influence, and often distort, people's perceptions of others.

Effects of Physical Appearance

PSYK TREK
SIM10

"You shouldn't judge a book by its cover." People know better than to let physical attractiveness determine their perceptions of others' personal qualities.

"Beauty is life's E-Z Pass."

Or do they? One recent study showed that good-looking people grab our attention almost immediately and hold on to our attention longer than less attractive individuals do (Maner et al., 2007). And a number of studies have demonstrated that judgments of others' personality are often swayed by their appearance, especially their physical attractiveness. People tend to ascribe desirable personality characteristics to those who are good looking, seeing them as more sociable, friendly, poised, warm, and well adjusted than those who are less attractive (Eagly et al., 1991; van Leeuwen & Macrae, 2004). In reality, research findings suggest that little correlation exists between attractiveness and personality traits (Feingold, 1992). Why do we inaccurately assume that a connection exists between good looks and personality? One reason is that extremely attractive people are vastly overrepresented in the entertainment media, where they are mostly portrayed in a highly favorable light (Smith, McIntosh, & Bazzini, 1999).

You might guess that physical attractiveness would influence perceptions of competence less than perceptions of personality, but the data suggest otherwise. A thorough review of the relevant research found that people have a surprisingly strong tendency to view good-looking individuals as more competent than less attractive individuals (Langlois et al., 2000). This bias literally pays off for good-looking people, as they tend to secure better jobs and earn higher salaries than less attractive individuals (Collins & Zebrowitz, 1995; Senior et al., 2007). For example, research on attorneys whose law school

class photos were evaluated by independent raters found that physical attractiveness boosted their actual income by 10%–12% (Engemann & Owyang, 2005). Fortunately, not all trait inferences are influenced by physical attractiveness. For instance, good looks seem to have relatively little impact on perceptions of honesty and integrity (Eagly et al., 1991).

Judgments of people's faces seem to be particularly important, as recent evidence suggests that these judgments are associated with significant outcomes in the real world. For example, one study found that perceptions of competence based solely on facial appearance predicted the outcomes of U.S. congressional elections surprisingly well (Todorov et al., 2005). Naive participants rated the competence of political candidates from all over the country based on brief exposures to head shots. The candidates who were viewed as more competent ended up winning 72% of Senate races and 67% of House races. In another study, participants rated the competence/power of 100 chief executive officers (CEOs) of large companies based on their facial appearance (Rule & Ambady, 2008). These ratings correlated .34 with the corporate profits of the CEOs' companies. Thus, perceptions of personality based on facial features are associated with objective measures of successful performance in important arenas of life.

Moreover, studies indicate that social perceptions based on facial appearance are formed in the blink of an eye. You might guess that people would need 20–30 seconds to size someone up, but a recent, compelling study demonstrated that it only takes a tenth of a second to draw inferences about individuals based on facial features. Willis and Todorov (2006) asked subjects to assess traits such as competence, trustworthiness, and aggressiveness based on brief exposures (1/10 of a second, half a second, or one second) to facial photographs. They compared these assessments to judgments of the same photos made by other participants who were given no time constraints and found that the instant judgments were highly correlated with the leisurely judgments. Thus, first impressions based on faces can occur almost instantly.

Stereotypes

Stereotypes can have a dramatic effect on the process of person perception. **Stereotypes are widely held beliefs that people have certain characteristics because of their membership in a particular group.** The most common stereotypes in our society are those based on sex, age, and membership in ethnic or occupational groups. People who subscribe

DILBERT

to traditional *gender stereotypes* tend to assume that women are emotional, submissive, illogical, and passive, while men are unemotional, dominant, logical, and aggressive. *Age stereotypes* suggest that elderly people are slow, feeble, rigid, forgetful, and asexual. Notions that Jews are mercenary, Germans are methodical, and Italians are passionate are examples of common *ethnic stereotypes. Occupational stereotypes* suggest that lawyers are manipulative, accountants are conforming, artists are moody, and so forth.

Stereotyping is a normal cognitive process that is usually automatic and that saves on the time and effort required to get a handle on people individually (Devine & Monteith, 1999; Operario & Fiske, 2001). Stereotypes save energy by simplifying our social world. However, this conservation of energy often comes at some cost in terms of accuracy (Wigboldus, Dijksterhuis, & Knippenberg, 2003). Stereotypes tend to be broad overgeneralizations that ignore the diversity within social groups and foster inaccurate perceptions of people (Hilton & von Hippel, 1996). Obviously, not all males, Jews, and lawyers behave alike. Most people who subscribe to stereotypes realize that not all members of a group are identical. For instance, they may admit that some men aren't competitive, some Jews aren't mercenary, and some lawyers aren't manipulative. However, they may still tend to assume that males, Jews, and lawyers are *more likely* than others to have these characteristics. Even if stereotypes mean only that people think in terms of slanted *probabilities,* their expectations may lead them to misperceive individuals with whom they interact. As we've noted in previous chapters, perception is subjective, and people often see what they expect to see.

Subjectivity in Person Perception

Stereotypes create biases in person perception that often lead to confirmation of people's expectations about others. If someone's behavior is ambiguous, people are likely to interpret what they see in a way that's consistent with their expectations (Olson, Roese, & Zanna, 1996). Thus, after dealing with a pushy female customer, a salesman who holds traditional gender stereotypes might characterize the woman as "emotional." In contrast, he might characterize a male who exhibits the same pushy behavior as "aggressive."

People not only see what they expect to see, they also tend to overestimate how often they see it (Johnson & Mullen, 1994; Shavitt et al., 1999). *Illusory correlation* **occurs when people estimate that they have encountered more confirmations of an association between social traits than they have actually seen.** People also tend to underestimate the number of disconfirmations they have encountered, as illustrated by statements like "I've never met an honest lawyer." One recent study showed that it takes only one instance of unusual or memorable behavior on the part of someone from an unfamiliar group to create an illusory correlation between that behavior and that group (Risen, Gilovich, & Dunning, 2007). Thus, illusory correlations routinely make contributions to stereotypes of various groups.

Memory processes can contribute to confirmatory biases in person perception in a variety of ways. Often, individuals selectively recall facts that fit with their stereotypes (Fiske, 1998; Quinn, Macrae, & Bodenhausen, 2003). Evidence for such a tendency was found in a study by Cohen (1981). In this experiment, participants watched a videotape of a woman, described as either a waitress or a librarian, who engaged in a variety of activities, including listening to classical music, drinking beer, and watching TV. When asked to recall what the woman did during the filmed sequence, participants tended to remember activities consistent with their stereotypes of waitresses and librarians. For instance, subjects who thought the woman was a waitress tended to recall her beer drink-

ing, while subjects who thought she was a librarian tended to recall her listening to classical music.

An Evolutionary Perspective on Bias in Person Perception

Why is the process of person perception riddled with bias? Evolutionary psychologists argue that many of the biases seen in social perception were adaptive in humans' ancestral environment (Krebs & Denton, 1997). For example, they argue that person perception is swayed by physical attractiveness because attractiveness was associated with reproductive potential in women and with health, vigor, and the accumulation of material resources in men.

What about the human tendency to automatically categorize others? Evolutionary theorists attribute this behavior to our distant ancestors' need to quickly separate friend from foe. They assert that humans are programmed by evolution to immediately classify people as members of an *ingroup*—a group that one belongs to and identifies with, or as members of an *outgroup*—a group that one does not belong to or identify with. This crucial categorization is thought to structure subsequent perceptions. As Krebs and Denton (1997) put it, "It is as though the act of classifying others as ingroup or outgroup members activates two quite different brain circuits" (p. 27). In-group members tend to be viewed in a favorable light, whereas outgroup members tend to be viewed in terms of various negative stereotypes. According to Krebs and Denton, these negative stereotypes ("They are inferior; they are all alike; they will exploit us") move outgroups out of our domain of empathy, so we feel justified in not liking them or discriminating against them.

Thus, evolutionary psychologists ascribe much of the bias in person perception to cognitive mechanisms that have been shaped by natural selection. Their speculation is thought provoking, but empirical work is needed to test their hypotheses.

REVIEW of Key Learning Goals

16.1 People's perceptions of a person can be distorted by his or her physical appearance. People tend to attribute desirable characteristics, such as intelligence, competence, warmth, and friendliness, to those who are good looking. Perceptions of competence based on facial appearance are particularly important. Social perceptions based on facial features can be formed in the blink of an eye.

16.2 Stereotypes are widely held beliefs that others will have certain characteristics because of their membership in a specific group. Gender, age, ethnic, and occupational stereotypes are common. In interacting with others, stereotypes may lead people to see what they expect to see. People also tend to overestimate how often their expectations are confirmed, a phenomenon called the illusory correlation effect.

16.3 Evolutionary psychologists argue that many biases in person perception were adaptive in humans' ancestral past. The human tendency to automatically categorize others may reflect the primitive need to quickly separate friend from foe.

Attribution Processes: Explaining Behavior

It's Friday evening and you're sitting around at home feeling bored. You call a few friends to see whether they'd like to go out. They all say that they'd love to go, but they have other commitments and can't. Their commitments sound vague, and you feel that their reasons for not going out with you are rather flimsy. How do you explain these rejections? Do your friends really have commitments? Are they worn out by school and work? When they said that they'd love to go, were they being sincere? Or do they find you boring? Could they be right? Are you boring? These questions illustrate a process that people engage in routinely: the explanation of behavior. *Attributions* play a key role in these explanatory efforts, and they have significant effects on social relations.

What are attributions? *Attributions* are inferences that people draw about the causes of events, others' behavior, and their own behavior. If you conclude that a friend turned down your invitation because she's overworked, you have made an attribution about the cause of her behavior (and, implicitly, have rejected other possible explanations). If you conclude that you're stuck at home with nothing to do because you failed to plan ahead, you've made an attribution about the cause of an event (being stuck at home). If you conclude that you failed to plan ahead because you're a procrastinator, you've made an attribution about the cause of your own behavior. People make attributions mainly because they have a strong need to understand their experiences. They want to make sense out of their own behavior, others' actions, and the events in their lives. In this section, we'll take a look at some of the patterns seen when people make attributions.

Key Learning Goals

16.4 Explain what attributions are, and distinguish between internal and external attributions.

16.5 Summarize Weiner's theory of attributions for success and failure.

16.6 Identify several types of bias in patterns of attribution.

16.7 Describe cultural variations in attributional tendencies.
Internal Versus External Attributions

Fritz Heider

"*Often the momentary situation which, at least in part, determines the behavior of a person is disregarded and the behavior is taken as a manifestation of personal characteristics.*"

Fritz Heider (1958) was the first to describe how people make attributions. He asserted that people tend to locate the cause of behavior either *within a person,* attributing it to personal factors, or *outside a person,* attributing it to environmental factors.

Elaborating on Heider's insight, various theorists have agreed that explanations of behavior and events can be categorized as internal or external attributions (Jones & Davis, 1965; Kelley, 1967; Weiner, 1974). *Internal attributions* ascribe the causes of behavior to personal dispositions, traits, abilities, and feelings. *External attributions* ascribe the causes of behavior to situational demands and environmental constraints. For example, if a friend's business fails, you might attribute it to his or her lack of business acumen (an internal, personal factor) or to negative trends in the nation's economic climate (an external, situational explanation). Parents who find out that their teenage son has just banged up the car may blame it on his carelessness (a personal disposition) or on slippery road conditions (a situational factor).

Internal and external attributions can have a tremendous impact on everyday interpersonal interactions. Blaming a friend's business failure on poor business acumen as opposed to a poor economy will have a great impact on how you view your friend.

Likewise, if parents attribute their son's automobile accident to slippery road conditions, they're likely to deal with the event very differently than if they attribute it to his carelessness.

Attributions for Success and Failure

Some psychologists have sought to discover additional dimensions of attributional thinking besides the internal-external dimension. After studying the attributions that people make in explaining success and failure, Bernard Weiner (1980, 1986, 1994) concluded that people often focus on the *stability* of the causes underlying behavior. According to Weiner, the stable-unstable dimension in attribution cuts across the internal-external dimension, creating four types of attributions for success and failure, as shown in Figure 16.1.

Let's apply Weiner's model to a concrete event. Imagine that you're contemplating why you failed to get a job that you wanted. You might attribute your setback to internal factors that are stable (lack of ability) or unstable (inadequate effort to put together an eye-catching résumé). Or you might attribute your setback to external factors that are stable (too much outstanding competition) or unstable (bad luck). If you got the job, your explanations for your success would fall into the same four categories: internal-stable (your excellent ability), internal-unstable (your hard work to assemble a superb résumé), external-stable (lack of top-flight competition), and external-unstable (good luck).

Bias in Attribution

Attributions are only inferences. Your attributions may not be the correct explanations for events. Paradoxical as it may seem, people often arrive at inaccurate explanations even when they contemplate the causes of *their own behavior.* Attributions ultimately represent *guesswork* about the causes of events, and these guesses tend to be slanted in certain directions. Let's look at the principal biases seen in attribution.

Actor-Observer Bias

Your view of your own behavior can be quite different from the view of someone else observing you. When an actor and an observer draw inferences about the causes of the actor's behavior, they often make different attributions. A common form of bias seen in observers is the *fundamental attribution error,* which refers to observers' bias in favor of

concept check 16.1

Analyzing Attributions

Check your understanding of attribution processes by analyzing possible explanations for an athletic team's success. Imagine that the women's track team at your school has just won a regional championship that qualifies it for the national tournament. Around the campus, you hear people attribute the team's success to a variety of factors. Examine the attributions shown below and place each of them in one of the cells of Weiner's model of attribution (just record the letter inside the cell). The answers are in Appendix A.

	Unstable cause (temporary)	Stable cause (permanent)
Internal cause		
External cause		

a. "They won only because the best two athletes on Central State's team were out with injuries—talk about good fortune!"
b. "They won because they have some of the best talent in the country."
c. "Anybody could win this region; the competition is far below average in comparison to the rest of the country."
d. "They won because they put in a great deal of last-minute effort and practice, and they were incredibly fired up for the regional tourney after last year's near-miss."

Figure 16.1

Weiner's model of attributions for success and failure. Weiner's model assumes that people's explanations for success and failure emphasize internal versus external causes and stable versus unstable causes. Examples of causal factors that fit into each of the four cells in Weiner's model are shown in the diagram.

SOURCE: Weiner, B., Friese, I., Kukla, A., Reed, L., & Rosenbaum, R. M. (1972). Perceiving the causes of success and failure. In E. E. Jones, D. E. Kanouse, H. H. Kelley, R. E. Nisbett, S. Valins, & B. Weiner (Eds.), *Perceiving the causes of behavior.* Morristown, NJ: General Learning Press. Used by permission of Bernard Weiner.

internal attributions in explaining others' behavior. Of course, in many instances, an internal attribution may not be an "error." However, observers have a curious tendency to overestimate the likelihood that an actor's behavior reflects personal qualities rather than situational factors (Krull, 2001). Why? One reason is that situational pressures may not be readily apparent to an observer. As Gilbert and Malone (1995) put it, "When one tries to point to a situation, one often stabs empty air" (p. 25). It is not that people assume that situational factors have little impact on behavior (Gawronski, 2004). Rather, it's that attributing others' behavior to their dispositions is a relatively effortless, almost automatic process, whereas explaining people's behavior in terms of situational factors requires more thought and effort (see **Figure 16.2**; Krull & Erickson, 1995). Another factor favoring internal attributions is that many people feel that few situations are so coercive that they negate all freedom of choice (Forsyth, 2004).

To illustrate the gap that often exists between actors' and observers' attributions, imagine that you're visiting your bank and you fly into a rage over a mistake made on your account. Observers who witness your rage are likely to make an internal attribution and infer that you are surly, temperamental, and quarrelsome. They may be right, but if asked, you'd probably attribute your rage to the frustrating situation. Perhaps you're normally a calm, easygoing person, but today you've been in line for 20 minutes, you just straightened out a similar error by the same bank last week, and you're being treated rudely by the teller. Observers are often unaware of historical and situational considerations such as these, so they tend to make internal attributions for another's behavior (Gilbert, 1998).

In contrast, the circumstances that have influenced an actor's behavior tend to be more apparent to the actor. Hence, actors are more likely than observers to locate the cause of their behavior in the situa-

Figure 16.2

An alternative view of the fundamental attribution error. According to Gilbert (1989) and others, the nature of attribution processes favors the *fundamental attribution error.* Traditional models of attribution assume that internal and external attributions are an either-or proposition requiring equal amounts of effort. In contrast, Gilbert maintains that people tend to automatically make internal attributions with little effort, and then they *may* expend additional effort to adjust for the influence of situational factors, which can lead to an external attribution. Thus, external attributions for others' behavior require more thought and effort, which makes them less common than personal attributions.

tion. In general, then, *actors favor external attributions for their behavior, whereas observers are more likely to explain the same behavior with internal attributions* (Jones & Nisbett, 1971; Krueger, Ham, & Linford, 1996).

That said, a recent study identified an interesting variable that appears to reduce observers' tendency to explain actors' behavior with internal attributions. That variable is whether the observers have experienced the same situation themselves (Balcetis & Dunning, 2008). Dealing with a specific situation gives people an opportunity to learn about the power of external forces in that situation. This knowledge makes them less likely to commit the fundamental attribution error in interpreting the behavior of others in the same situation. For example, people who have been tricked by a con artist, or who have suffered through a foreclosure, generally will be less likely to make internal attributions in explaining why others have experienced a similar fate.

Defensive Attribution   12a

In attempting to explain the calamities and setbacks that befall other people, an observer's tendency to make internal attributions may become even stronger than normal. Let's say that a friend gets mugged and severely beaten. You may attribute the mugging to your friend's carelessness or stupidity ("He should have known better than to be in that neighborhood at that time") rather than to bad luck. Why? Because if you attribute your friend's misfortune to bad luck, you have to face the ugly reality that it could just as easily happen to you. To avoid such disturbing thoughts, people often attribute mishaps to victims' negligence (Idisis, Ben-David, & Ben-Nachum, 2007; Salminen, 1992; Thornton, 1992).

Defensive attribution **is a tendency to blame victims for their misfortune, so that one feels less likely to be victimized in a similar way.** *Hindsight bias* probably contributes to this tendency, but blaming victims also helps people maintain their belief that they live in a just world, where they're unlikely to experience similar troubles (Lerner & Goldberg, 1999). The bias toward making defensive attributions can have unfortunate consequences. Blaming victims for their setbacks causes them to be seen in a negative light, and undesirable traits are unfairly attributed to them. Thus, it is assumed that burglary victims must be careless, that people who get fired must be incompetent, that poor people must be lazy, that rape victims must be seductive ("She probably asked for it"), and so on. As you can see, defensive attribution can lead to unwarranted derogation of victims of misfortune.

Self-Serving Bias   12a

The self-serving bias in attribution comes into play when people attempt to explain success and failure. This bias may either strengthen or weaken one's normal attributional tendencies, depending on whether one is trying to explain positive or negative

A common example of defensive attribution is the tendency to blame the homeless for their plight.

© Mark Peterson/Corbis

outcomes (Mezulis et al., 2004; Shepperd, Malone, & Sweeny, 2008). **The *self-serving bias* is the tendency to attribute one's successes to personal factors and one's failures to situational factors.** Interestingly, this bias grows stronger as time passes after an event, so that people tend to take progressively more credit for their successes and less responsibility for their failures (Burger, 1986). *In explaining failure, the usual actor-observer biases are apparent.* Actors tend to blame failures on unfavorable situational factors, while observers are more likely to attribute the same failures to the actors' personal shortcomings. *In explaining success, the usual actor-observer differences are reversed to some degree.* Actors make internal attributions to take credit for their accomplishments, whereas observers are more likely to assume that the actor benefited from favorable situational factors.

Culture and Attributional Tendencies

Do the patterns of attribution observed in subjects from Western societies transcend culture? More research is needed, but the preliminary evidence suggests not. Some interesting cultural disparities have emerged in research on attribution processes.

According to Harry Triandis (1989, 1994, 2001), cultural differences in *individualism* versus *collectivism* influence attributional tendencies as well as other aspects of social behavior. As noted in Chapter 12, ***individualism* involves putting personal goals ahead of group goals and defining one's identity in terms of personal attributes rather than group memberships.** In contrast, ***collectivism* involves putting group goals ahead of personal goals and defining one's identity in terms of the groups one belongs to** (such as one's family, tribe, work group, social class, and so on). In comparison to individualistic cultures, collectivist cultures place a higher priority on shared values and resources, cooperation, mutual interdependence, and concern for how one's actions will affect other group members. In childrearing, collectivist cultures emphasize the importance of obedience, reliability, and proper behavior, whereas individualistic cultures emphasize the development of independence, self-esteem, and self-reliance.

A variety of factors influence whether societies cherish individualism as opposed to collectivism. Among other things, increases in a culture's affluence, education, urbanization, and social mobility tend to foster more individualism (Triandis, 1994). Many contemporary societies are in transition, but generally speaking, North American and Western European cultures tend to be individualistic, whereas Asian, African, and Latin American cultures

tend to be collectivistic (Hofstede, 1980, 1983, 2001) (see **Figure 16.3**).

How does individualism versus collectivism relate to patterns of attribution? The evidence suggests that collectivist cultures may promote different attributional biases than individualistic cultures. For example, people from collectivist societies appear to be less prone to the *fundamental attribution error* than those from individualistic societies (Choi, Nisbett, & Norenzayan, 1999; Triandis, 2001). In Western cultures, people are viewed as autonomous individuals who are responsible for their actions. Endorsing beliefs such as "You can do anything you put your mind to" or "You have no one to blame but yourself," Westerners typically explain behavior in terms of people's personality traits and unique abilities. In contrast, collectivists, who value interdependence and obedience, are more likely to assume that one's behavior reflects adherence to group norms.

Research suggests that Asians view events in the context of webs of interdependent social relationships. This holistic perception of the world leads them to make more complex causal attributions than Westerners. This way of thinking also tends to make Asians more aware of the sometimes indirect and distant consequences of events, what one might refer to as unexpected *ripple effects* (Maddux & Yuki, 2006). For example, when asked about the consequences of a specific event, such as being laid off or being in an car accident, Asian subjects estimate that far more people will be affected than Western participants do.

Although the *self-serving bias* has been documented in a variety of cultures, it is particularly prevalent in individualistic, Western societies, where

Hofstede's rankings of national cultures' individualism		
Individualistic cultures	**Intermediate cultures**	**Collectivist cultures**
1. United States	19. Israel	37. Hong Kong
2. Australia	20. Spain	38. Chile
3. Great Britain	21. India	40. Singapore
4. Canada	22. Argentina	40. Thailand
4. Netherlands	22. Japan	40. West Africa region
6. New Zealand	24. Iran	42. El Salvador
7. Italy	25. Jamaica	43. South Korea
8. Belgium	26. Arab region	44. Taiwan

14. Switzerland	32. Mexico	50. Venezuela
15. West Germany	34. East Africa region	51. Panama
16. South Africa	34. Portugal	52. Ecuador
17. Finland	34. Yugoslavia	53. Guatemala
18. Austria	36. Malaysia	

Figure 16.3
Individualism versus collectivism around the world. Hofstede (1980, 1983, 2001) used survey data from over 100,000 employees of a large, multinational corporation to estimate the emphasis on individualism versus collectivism in 50 nations and 3 regions. His large, diverse international sample remains unequaled to date. In the figure, cultures are ranked in terms of how strongly they embraced the values of individualism. As you can see, Hofstede's estimates suggest that North American and Western European nations tend to be relatively individualistic, whereas more collectivism is found in Asian, African, and Latin American countries.

concept check 16.2

Recognizing Bias in Social Cognition

Check your understanding of bias in social cognition by identifying various types of errors that are common in person perception and attribution. Imagine that you're a nonvoting student member of a college committee at Southwest State University that is hiring a new political science professor. As you listen to the committee's discussion, you hear examples of (a) the illusory correlation effect, (b) stereotyping, (c) the fundamental attribution error, and (d) defensive attribution. Indicate which of these is at work in the excerpts from committee members' deliberations below. The answers are in Appendix A.

_____ 1. "I absolutely won't consider the fellow who arrived 30 minutes late for his interview. Anybody who can't make a job interview on time is either irresponsible or hopelessly disorganized. I don't care what he says about the airline messing up his reservations."

_____ 2. "You know, I was very, very impressed with the young female applicant, and I would love to hire her, but every time we add a young woman to the faculty in liberal arts, she gets pregnant within the first year." The committee chairperson, who has heard this line from this professor before replies, "You always say that, so I finally did a systematic check of what's happened in the past. Of the last 14 women hired in liberal arts, only one has become pregnant within a year."

_____ 3. "The first one I want to rule out is the guy who's been practicing law for the last ten years. Although he has an excellent background in political science, I just don't trust lawyers. They're all ambitious, power-hungry, manipulative cutthroats. He'll be a divisive force in the department."

_____ 4. "I say we forget about the two candidates who lost their faculty slots in the massive financial crisis at Western Polytechnic last year. I know it sounds cruel, but they brought it on themselves with their fiscal irresponsibility over at Western. Thank goodness we'll never let anything like that happen around here. As far as I'm concerned, if these guys couldn't see that crisis coming, they must be pretty dense."

an emphasis on competition and high self-esteem motivates people to try to impress others, as well as themselves (Mezulis et al., 2004). In contrast, Japanese subjects exhibit a *self-effacing bias* in explaining success (Akimoto & Sanbonmatsu, 1999; Markus & Kitayama, 1991), as they tend to attribute their successes to help they receive from others or to the ease of the task, while downplaying the importance of their ability. When they fail, Japanese subjects tend to be more self-critical than subjects from individualistic cultures (Heine & Renshaw, 2002).

REVIEW of Key Learning Goals

16.4 Attributions are inferences about the causes of events and behavior. Individuals make attributions to understand their social world. Attributions can be classified as internal or external. Internal attributions ascribe behavior to personal dispositions and traits, whereas external attributions locate the cause of behavior in the environment.

16.5 Weiner's model proposes that attributions for success and failure should be analyzed in terms of the stability of causes, as well as along the internal-external dimension, yielding four possible types of attributions: internal-stable, internal-unstable, external-stable, and external-unstable.

16.6 Observers favor internal attributions to explain another's behavior, which is called the fundamental attribution error, while actors favor external attributions to explain their own behavior. In defensive attribution, people unfairly blame victims for their misfortune (with internal attributions) to reduce their own feelings of vulnerability. The self-serving bias is the tendency to attribute one's good outcomes to personal factors and one's bad outcomes to situational factors.

16.7 Cultures vary in their emphasis on individualism as opposed to collectivism, and these differences appear to influence attributional tendencies. The fundamental attribution error and the self-serving bias in attribution may be more prevalent in Western cultures that are high in individualism.

Close Relationships: Liking and Loving

Key Learning Goals

16.8 Evaluate the role of physical attractiveness and similarity in attraction.

16.9 Clarify the role of reciprocity and romantic ideals in attraction.

16.10 Distinguish between passionate love and companionate love and between intimacy and commitment.

16.11 Outline the evidence on love as a form of attachment.

16.12 Discuss cultural variations in close relationships and how the Internet has affected romantic relationships.

16.13 Understand evolutionary analyses of mating preferences and tactics.

"I just don't know what she sees in him. She could do so much better for herself. I suppose he's a nice guy, but they're just not right for each other." Can't you imagine Muffy's friends making these comments in discussing her relationship with Jake? You've probably heard similar remarks on many occasions. These comments illustrate people's interest in analyzing the dynamics of attraction. *Interpersonal attraction refers to positive feelings toward another.* Social psychologists use this term broadly to encompass a variety of experiences, including liking, friendship, admiration, lust, and love. In this section, we'll analyze key factors that influence attraction and examine some theoretical perspectives on the mystery of love.

Key Factors in Attraction

Many factors influence who is attracted to whom. Here we'll discuss factors that promote the development of liking, friendship, and love. Although these are different types of attraction, the interpersonal dynamics at work in each are largely similar.

Physical Attractiveness

It is often said that "beauty is only skin deep," but the empirical evidence suggests that most people don't really believe that homily (Fitness, Fletcher, & Overall, 2003). The importance of physical attractiveness was demonstrated in a study in which unacquainted men and women were sent off on a

"get-acquainted" date (Sprecher & Duck, 1994). The investigators were mainly interested in how communication might affect the process of attraction, but to put this factor in context they also measured subjects' perceptions of their date's physical attractiveness and similarity to themselves. They found that the quality of communication during the date did have some effect on females' interest in friendship, but the key determinant of romantic attraction for both sexes was the physical attractiveness of the other person. Consistent with this finding, research has shown, as one might expect, that attractive people of both sexes enjoy greater mating success than their less attractive peers (Rhodes, Simmons, & Peters, 2005). Many other studies have demonstrated the singular prominence of physical attractiveness in the initial stage of dating and have shown that it continues to influence the course of commitment as relationships evolve (McNulty, Neff, & Karney, 2008; Patzer, 2006). In the realm of romance, being physically attractive appears to be more important for females' desirability (Gottschall, 2007; Regan, 2003). For example, in a study of college students (Speed & Gangestad, 1997), the correlation between romantic popularity (assessed by peer ratings) and physical attractiveness was higher for females (.76) than for males (.47).

Although people prefer physically attractive partners in romantic relationships, they may consider their own level of attractiveness in pursuing dates. What people want in a partner may be different from what they are willing to settle for (Regan, 1998). **The *matching hypothesis* proposes that males and females of approximately equal physical attractiveness are likely to select each other as partners.** The matching hypothesis is supported by evidence that married couples tend to be very similar in level of physical attractiveness (Feingold, 1988b). Interestingly, people expect that individuals who are similar in attractiveness will be more satisfied as couples and less likely to break up (Garcia & Khersonsky, 1996), although a recent study of actual married couples failed to support this notion (McNulty et al., 2008).

Similarity Effects

Is it true that "birds of a feather flock together," or do "opposites attract"? Research provides far more support for the former than the latter. Married and dating couples tend to be similar in age, race, religion, social class, education, intelligence, physical attractiveness, values, and attitudes (Kalmijn, 1998; Watson et al., 2004). Similarity is also seen among friends. For instance, adult friends tend to be relatively similar in terms of income, education, occu-

According to the matching hypothesis, males and females who are similar in physical attractiveness are likely to be drawn together. This type of matching may also influence the formation of friendships.

pational status, ethnicity, and religion (Blieszner & Adams, 1992). Among romantic couples, similarity in *personality* appears to be modest (Luo & Klohnen, 2005). However, some couples are more similar in personality than others, and this convergence in personality does correlate moderately with relationship satisfaction (Gonzaga, Campos, & Bradbury, 2007).

The most obvious explanation for these correlations is that similarity causes attraction. Laboratory experiments on *attitude similarity,* conducted by Donn Byrne and his colleagues, suggest that similarity *does* cause attraction (Byrne, 1997; Byrne, Clore, & Smeaton, 1986). However, research also suggests that attraction can foster similarity (Anderson, Keltner, & John, 2003). For example, Davis and Rusbult (2001) found that dating partners gradually modify their attitudes in ways that make them more congruent, a phenomenon they called *attitude alignment.* Moreover, people in stable, satisfying intimate relationships tend to subjectively overestimate how similar they and their partners are (Murray et al.,

"It would never work out between us, Tom—we're from two totally different tiers of the upper middle class."

2002). Wanting to believe that they have found a kindred spirit, they tend to assume that their partners are mirrors of themselves.

Reciprocity Effects

People often attempt to gain others' liking by showering them with praise and flattery. However, we've all heard that "flattery will get you nowhere." However, the evidence suggests that flattery will indeed get you somewhere, with some people, some of the time. In interpersonal attraction, *reciprocity* **involves liking those who show that they like you.** In general, research indicates that we tend to like those who show that they like us and that we tend to see others as liking us more if we like them. Thus, it appears that liking breeds liking and loving promotes loving (Sprecher, 1998).

Romantic Ideals

In the realm of romance, people want their partner to measure up to their ideals. These ideals spell out the personal qualities that one hopes to find in a partner, such as warmth, good looks, loyalty, high status, a sense of humor, and so forth. According to Simpson, Fletcher, and Campbell (2001), people routinely evaluate how close their intimate partners come to matching these ideal standards, and these evaluations influence how relationships progress. Consistent with this theory, research shows that the more closely individuals' perceptions of their partners match their ideals, the more satisfied they tend to be with their relationship—both in the early stages of dating (Fletcher, Simpson, & Thomas, 2000) and in stable, long-term relationships (Fletcher, Simpson, & Thomas, 1999). Moreover, the size of the discrepancy between ideals and perceptions predicts how much partners try to influence each other's behavior and whether a relationship will continue or dissolve (Fletcher et al., 2000; Overall, Fletcher, & Simpson, 2006).

Of course, these evaluations of how one's partner compares to one's ideals are subjective, leaving room for distortion. When people are highly invested in a relationship, they can reduce the discrepancy between their ideals and their perceptions either by lowering their standards or by making charitable evaluations of their partners. Research suggests that the latter strategy is more common. For example, in a study of 180 couples, Murray, Holmes, and Griffin (1996) found that most participants viewed their partners more favorably than the partners viewed themselves. Individuals' perceptions of their romantic partners seemed to reflect their ideals for a partner more than reality. As Boyes and Fletcher (2007) put it, "entrusting one's happiness to another person seems to require a leap of faith and the need to see one's partner through rose-colored glasses" (p. 286). Interestingly, research suggests that people are happier in their relationship when they idealize their partners and when their partners idealize them. This line of research suggests that small, positive illusions about one's partner may foster happier and more resilient romantic relationships (Miller, Niehuis, & Huston, 2006; Murray, 2001).

Perspectives on the Mystery of Love

Love has proven to be an elusive subject. It's difficult to define and study because there are many types of love (Berscheid, 2006). Nonetheless, psychologists have begun to make some progress in their study of love. Let's look at their theories and research.

Passionate and Companionate Love

Two early pioneers in research on love, Elaine Hatfield (formerly Walster) and Ellen Berscheid (Berscheid, 1988; Berscheid & Walster, 1978; Hatfield & Rapson, 1993), have proposed that romantic relationships are characterized by two kinds of love: passionate love and companionate love. *Passionate love* **is a complete absorption in another that includes tender sexual feelings and the agony and ecstasy of intense emotion.** Passionate love has its ups and downs, as it is associated with large swings in positive and negative emotions (Reis & Aron, 2008). *Companionate love* **is warm, trusting, tolerant affection for another whose life is deeply intertwined with one's own.** Passionate and companionate love *may* coexist, but they don't necessarily go hand in hand. Research suggests that, as a general rule, companionate love is more strongly related to relationship satisfaction than passionate love (Fehr, 2001).

The distinction between passionate and companionate love has been further refined by Robert Sternberg (1988a, 2006), who suggests that love has three facets rather than just two. He subdivides companionate love into intimacy and commitment. *Intimacy* **refers to warmth, closeness, and sharing in a relationship.** *Commitment* **is an intent to maintain a relationship in spite of the difficulties and costs that may arise.** Sternberg has mapped out the probable relations between the passage of time and the three components of love, as shown in **Figure 16.4.** Like Hatfield and Berscheid, he suspects that passion reaches its zenith in the early phases of love and then erodes. He believes that intimacy and commitment increase with time, although at different rates.

Research suggests that passionate love is a powerful motivational force that produces profound

12b

Ellen Berscheid

"The emotion of romantic love seems to be distressingly fragile. As a 16th-century sage poignantly observed, 'the history of a love affair is the drama of its fight against time.'"

changes in people's thinking, emotion, and behavior (Reis & Aron, 2008). Interestingly, brain-imaging research indicates that when people think about someone they are passionately in love with, these thoughts light up the dopamine circuits in the brain that are known to be activated by cocaine and other addictive drugs (Aron, Fisher, & Mashek, 2005). Perhaps that explains why passionate love sometimes resembles an addiction. Although passionate love is the glamorous face of love, commitment appears to be the crucial facet of love that is predictive of relationship stability. For example, declining commitment is associated with an increased likelihood of infidelity in dating relationships (Drigotas, Safstrom, & Gentilia, 1999). A study of dating couples who were followed for four years, found that participants' feelings of commitment were more predictive of whether they broke up than their ratings of their overall love (Sprecher, 1999). Interestingly, the participants who broke up indicated that their love had remained reasonably stable, but their commitment and satisfaction had declined.

Love as Attachment 12b

In another groundbreaking analysis of love, Cindy Hazan and Phillip Shaver (1987) looked not at the components of love but at similarities between love and *attachment relationships* in infancy. We noted in our chapter on human development (Chapter 11) that infant-caretaker bonding, or attachment,

emerges in the first year of life. Early attachments vary in quality, and *most* infants tend to fall into one of three groups, which depend in part on parents' caregiving styles (Ainsworth et al., 1978). A majority of infants develop a *secure attachment.* However, some are very anxious when separated from their caretaker, a syndrome called *anxious-ambivalent attachment.* A third group of infants, characterized by *avoidant attachment,* never bond very well with their caretaker (see **Figure 16.5**).

According to Hazan and Shaver, romantic love is an attachment process, and people's intimate relationships in adulthood follow the same form as their

Figure 16.4

Sternberg's view of love over time. In his theory of love, Robert Sternberg (1988a) hypothesizes that the various elements of love progress in different ways over the course of time. According to Sternberg, passion peaks early in a relationship, whereas intimacy and commitment typically continue to build gradually. (Graphs adapted from Trotter, 1986)

Parents' caregiving style	Infant attachment	Adult attachment style
Warm/responsive She/he was generally warm and responsive; she/he was good at knowing when to be supportive and when to let me operate on my own; our relationship was almost always comfortable, and I have no major reservations or complaints about it.	**Secure attachment** An infant-caregiver bond in which the child welcomes contact with a close companion and uses this person as a secure base from which to explore the environment	**Secure** I find it relatively easy to get close to others and am comfortable depending on them and having them depend on me. I don't often worry about being abandoned or about someone getting too close to me.
Cold/rejecting She/he was fairly cold and distant, or rejecting, not very responsive; I wasn't her/his highest priority, her/his concerns were often elsewhere; it's possible that she/he would just as soon not have had me.	**Avoidant attachment** An insecure infant-caregiver bond, characterized by little separation protest and a tendency of the child to avoid or ignore the caregiver	**Avoidant** I am somewhat uncomfortable being close to others; I find it difficult to trust them, difficult to allow myself to depend on them. I am nervous when anyone gets too close, and often love partners want me to be more intimate than I feel comfortable being.
Ambivalent/inconsistent She/he was noticeably inconsistent in her/his reactions to me, sometimes warm and sometimes not; she/he had her/his own agenda, which sometimes got in the way of her/his receptiveness and responsiveness to my needs; she/he definitely loved me but didn't always show it in the best way.	**Anxious/ambivalent attachment** An insecure infant-caregiver bond, characterized by strong separation protest and a tendency of the child to resist contact initiated by the caregiver, particularly after a separation	**Anxious/ambivalent** I find that others are reluctant to get as close as I would like. I often worry that my partner doesn't really love me or won't want to stay with me. I want to merge completely with another person, and this desire sometimes scares people away.

Figure 16.5

Infant attachment and romantic relationships. According to Hazan and Shaver (1987), people's romantic relationships in adulthood are similar in form to their attachment patterns in infancy, which are determined in part by parental caregiving styles. The theorized relations between parental styles, attachment patterns, and intimate relations are outlined here. (Data for parental caregiving styles and adult attachment styles based on Hazan and Shaver, 1986, 1987; infant attachment patterns adapted from Shaffer, 1985)

attachments in infancy. According to their theory, a person who had an anxious-ambivalent attachment in infancy will tend to have romantic relations marked by anxiety and ambivalence in adulthood. In other words, people relive their early bonding experiences with their parents in their adult romantic relationships.

Hazan and Shaver's (1987) initial survey study provided striking support for their theory. They found that adults' love relationships could be sorted into groups that paralleled the three patterns of attachment seen in infants. *Secure adults* (56% of the subjects) found it relatively easy to get close to others, described their love relations as trusting, rarely worried about being abandoned, and reported the fewest divorces. *Anxious-ambivalent adults* (20% of the subjects) reported a preoccupation with love accompanied by expectations of rejection and described their love relations as volatile and marked by jealousy. *Avoidant adults* (24% of the subjects) found it difficult to get close to others and described their love relations as lacking intimacy and trust. Research eventually showed that attachment patterns are reasonably stable over time (Fraley, 2002) and that people's working models of attachment are carried forward from one relationship to the next (Brumbaugh & Fraley, 2006), supporting the notion that individuals' infant attachment experiences shape their intimate relations in adulthood.

After years of research on adult attachment, many theorists now believe that attachment is best conceptualized in terms of where people fall on two continuous dimensions: attachment anxiety and attachment avoidance (Fraley & Shaver, 2000; Mikulincer, 2006). *Attachment anxiety* reflects how much people worry that their partners will not be available when needed. This vigilance about abandonment stems, in part, from their doubts about their lovability. *Attachment avoidance* reflects the degree to which people feel uncomfortable with closeness and intimacy and therefore tend to maintain emotional distance from their partners.

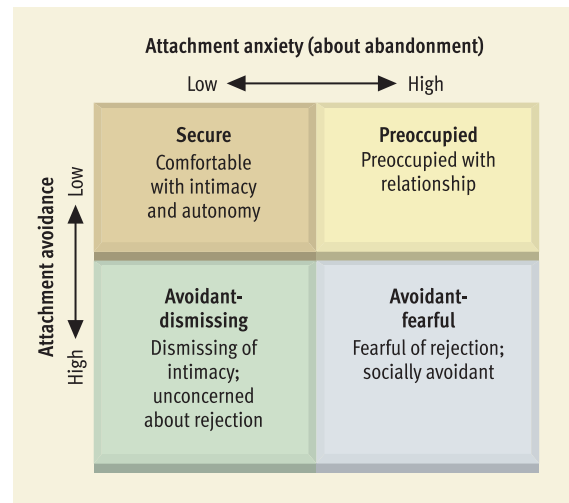
Although this new approach was intended to restructure thinking about attachment in terms of continuous dimensions, it is also compatible with the original emphasis on attachment style subtypes. But it yields one additional subtype, as people who score high or low on the two dimensions can be divided into four attachment styles. As explained in **Figure 16.6**, this scheme yields a *secure* subtype, a *preoccupied* subtype that is essentially equivalent to the original anxious-ambivalent subtype, and two variations on avoidant attachment: *avoidant-dismissing* and *avoidant-fearful*. Currently, some researchers measure attachment style in terms of the original


Figure 16.6

Attachment styles and their underlying dimensions. Attachment styles can be viewed in terms of where people fall along two continuous dimensions that range from low to high: attachment avoidance and attachment anxiety (about abandonment). This system yields four attachment styles, which are described in the four cells shown here. (Adapted from Brennan, Clark, & Shaver, 1998; Fraley & Shaver, 2000)

three subtypes, whereas others measure attachment in terms of the two dimensions that can generate four subtypes.

Research on the correlates of adult attachment styles has grown exponentially since the mid-1990s. Consistent with the original theory, research has shown that securely attached individuals have more committed, satisfying, interdependent, well-adjusted, and longer-lasting relationships compared to people with anxious-ambivalent or avoidant attachment styles (Feeney, 1999). Moreover, studies have shown that people with different attachment styles are predisposed to think, feel, and behave differently in their relationships (Collins & Allard, 2001). For example, anxious-ambivalent people tend to report more intense emotional highs and lows in their romantic relationships. They also report having more conflicts with their partners, that these conflicts are especially stressful, and that these conflicts often have a negative impact on how they feel about their relationship (Campbell et al., 2005). In a similar vein, attachment anxiety promotes *excessive reassurance seeking*—the tendency to persistently ask for assurances from partners that one is worthy of love (Shaver, Schachner & Mikulincer, 2005).

Attachment style also appears to be intimately related to people's patterns of sexual interaction. People with secure attachment tend to be more comfortable with their sexuality, more motivated to show love for their partner during sex, more open to sexual exploration, more likely to have sex in

the context of committed relationships, and less accepting of casual sex (Cooper et al., 2006; Shaver & Mikulincer, 2006). In contrast, people high in attachment anxiety tend to have sex to reduce their feelings of insecurity and are more likely to consent to unwanted sexual acts and less likely to practice safe sex (Cooper et al., 2006; Schachner & Shaver, 2004). People high in avoidant attachment tend to engage in more casual sex in an effort to impress their peers, and they are more likely to use sex to manipulate their partners (Schachner & Shaver, 2004; Shaver & Mikulincer, 2006).

Reactions to romantic breakups also tend to vary depending on attachment style. People who are high in attachment anxiety have much more difficulty than others in dealing with the dissolution of romantic relationships. They report greater emotional and physical distress, greater preoccupation with the former partner, more attempts to regain the lost partner, more angry and vengeful behavior, and more maladaptive coping responses, such as using alcohol and drugs to cope with the loss (Davis, Shaver, & Vernon, 2003).

Studies have further suggested that attachment patterns may have far-reaching repercussions that extend into many aspects of people's lives besides their romantic relationships. For instance, people with secure attachments tend to have high self-esteem and to be relatively well adjusted. In contrast, people with avoidant or anxious-ambivalent attachments tend to be overrepresented in groups suffering from depression, eating disorders, and other types of psychopathology (Crowell, Fraley, & Shaver, 1999). Attachment security promotes compassionate feelings and values and more helping behavior when people are in need (Mikulincer & Shaver, 2005). Researchers have also found correlations between attachment styles and gender roles (Schwartz, Waldo, & Higgins, 2004), religious beliefs (Kirkpatrick, 2005), health habits (Huntsinger & Luecken, 2004), reactions to stressful events (Powers et al., 2006), styles of coping with stress (Howard & Medway, 2004), vulnerability to burnout (Pines, 2004), and leadership qualities (Davidovitz et al. 2007). Thus, Hazan and Shaver's innovative ideas about the long-term effects of infant attachment experiences have triggered an avalanche of thought-provoking research.

Culture and Close Relationships

Relatively little cross-cultural research has been conducted on the dynamics of close relationships. The limited evidence suggests both similarities and differences between cultures in romantic relationships (Hendrick & Hendrick, 2000; Schmitt, 2005). For the most part, similarities have been seen when research has focused on what people look for in prospective mates. As we discussed in Chapter 10, David Buss (1989, 1994a) has collected data on mate preferences in 37 divergent cultures and found that people all over the world value mutual attraction, kindness, intelligence, emotional stability, dependability, and good health in a mate. Buss also found that gender differences in mating priorities are nearly universal, with males placing more emphasis on physical attractiveness and females putting a higher priority on social status and financial resources.

Cultures vary, however, in their emphasis on love—especially passionate love—as a prerequisite for marriage. Although romantic love appears to be found in all cultures (Buss, 2006), passionate love as the basis for marriage is an 18th-century invention of Western culture (Stone, 1977). As Hatfield and Rapson (1993) note, "Marriage-for-love represents an ultimate expression of individualism" (p. 2). In contrast, marriages arranged by families and other go-betweens remain common in cultures high in collectivism, including India, Japan, and China (Hatfield, Rapson, & Martel, 2007). This practice is declining in some societies as a result of Westernization, but in collectivist societies people contemplating marriage still tend to think in terms of "What will my parents and other people say?" rather than "What does my heart say?" (Triandis, 1994). Although romantic love is routinely seen in collectivist societies (Lieberman & Hatfield, 2006), subjects from societies high in individualism tend to report that romantic love is more important for marriage than subjects from collectivist cultures do (Dion & Dion, 2006; Levine et al., 1995).

Marriages based on romantic love are the norm in Western cultures, whereas arranged marriages prevail in collectivist cultures.

The Internet and Close Relationships

Figure 16.7
Dating-related activities online. Researchers asked Internet users who were single and looking for a romantic partner how they used the Internet (including e-mail and instant messaging) for dating (Madden & Lenhart, 2006). Flirting and going to an online dating website were most frequently mentioned. Most respondents engaged in three or fewer of these activities.

Adapted from Madden, M. & Lenhart, A. (2006). *Online dating.* Retrieved April 29, 2007 from http://www.pewinternet.org/pdfs/PIP_Online_Dating.pdf. (Dating-Related Activities Online table, p. 5). Reprinted by permission of Pew Internet & American Life Project. Washington, D.C.

In recent years the Internet has dramatically expanded opportunities for people to meet and develop close relationships through social networking services (Myspace, Friendster), online dating services, e-mail, chat rooms, and news groups. Some critics worry that this trend will undermine face-to-face interactions and that many people will be lured into dangerous liaisons by unscrupulous people. But research to date generally paints a positive picture of the Internet's impact on people's connections with one another (Whitty, 2008). For example, the Internet offers a wealth of opportunities to interact for those who suffer from physical infirmities or social anxieties (McKenna & Bargh, 2000). Also, Internet groups provide a safer venue than real life for individuals with stigmatized identities (for example, gay people) to interact and receive support.

One survey based on a nationally representative sample of American adults reported that 31% knew someone who had used a dating website and 11% had visited such a site to meet people (Madden & Lenhart, 2006). Among those who used online dating sites, a majority (52%) reported "mostly positive" experiences, although a considerable portion (29%) had "mostly negative" experiences. This report also asked the Internet users who said they were single and looking for a romantic partner to identify how they used the Internet for dating. You can see their responses in **Figure 16.7**.

Although critics are concerned that Internet relationships are superficial, research suggests that virtual relationships are just as intimate as face-to-face ones and are sometimes even closer (Bargh, McKenna, & Fitzsimons, 2002). Moreover, many virtual relationships evolve into face-to-face interactions (Boase & Wellman, 2006). Researchers find that romantic relationships that begin on the Internet seem to be just as stable over two years as traditional relationships ((McKenna, Green, & Gleason, 2002).

The differences between Internet and face-to-face communication may undermine some established principles of relationship development (Bargh & McKenna, 2004). For example, good looks and physical proximity are powerful factors in initial attraction in the real world. On the Internet, where people often form relationships sight-unseen, these factors may be less influential. Online, where people rely on self-disclosure to develop relationships, similarity of interests and values assumes more power than it does in face-to-face relationships. Because the Internet can foster anonymity, people often take greater risks in self-disclosure (Johnson & Paine, 2007). Thus, feelings of intimacy can develop more quickly. But instant intimacy can create uncomfortable feelings if a face-to-face meeting ensues—that is, meeting with a stranger who knows "too much" about you (Hamilton, 1999). Of course, face-to-face meetings can also go smoothly.

Anonymity also allows people to construct a virtual identity. Obviously, this can be a problem if one person adopts a fictional persona and an-

other assumes that it is authentic and begins to take the relationship seriously. A related concern is the truthfulness of online daters. In one survey, 25% of online daters admitted to using deception (Brym & Lenton, 2001). Yet, a whopping 86% of participants at one online dating site felt that others misrepresented their physical appearance (Gibbs, Ellison, & Heino, 2006). Admittedly, creating an accurate online representation of oneself can be a complex process: People want to put their best self forward to attract potential dates, but they also need to present themselves authentically if they expect to eventually meet face to face (Gibbs, et al., 2006). One study found that online daters dealt with this tension by constructing profiles that reflected their "ideal self" rather than their "actual self" (Ellison, Heino, & Gibbs, 2006). The most common factors that online daters misrepresent are age, appearance, and marital status (Brym & Lenton, 2001).

An Evolutionary Perspective on Attraction

Evolutionary psychologists have a great deal to say about heterosexual attraction. For example, they assert that physical appearance is an influential determinant of attraction because certain aspects of good looks can be indicators of sound health, good genes, and high fertility, all of which can contribute to reproductive potential (Soler et al., 2003; Sugiyama, 2005). Consistent with this analysis, recent research has found that some standards of attractiveness are more consistent across cultures than previously believed (Sugiyama, 2005). For example, *facial symmetry* seems to be a key element of attractiveness in highly diverse cultures (Fink & Penton-Voak, 2002). Facial symmetry is thought to be valued because a variety of environmental insults and developmental abnormalities are associated with physical asymmetries, which may serve as markers of relatively poor genes or health (Fink et al., 2006). Another facet of appearance that may transcend culture is *women's waist-to-hip ratio*. Around the world, men seem to prefer women with a moderately low waist-to-hip ratio, which appears to be a meaningful correlate of females' reproductive potential (Hughes & Gallup, 2003; Sugiyama, 2005), as it signals that a woman is healthy, young, and not pregnant.

The most thoroughly documented findings on the evolutionary bases of heterosexual attraction are those on gender differences in humans' mating preferences. Consistent with the notion that humans are programmed by evolution to behave in ways that enhance their reproductive fitness, evidence indicates that men generally are more interested than women in seeking youthfulness and physical attractiveness in their mates because these traits should be associated with greater reproductive potential (see Chapter 10). On the other hand, research shows that women place a greater premium on prospective mates' ambition, social status, and financial potential because these traits should be associated with the ability to invest material resources in children (Li et al., 2002; Shackelford, Schmitt, & Buss, 2005). The degree to which these trends transcend history and culture was driven home by a study that examined the mate preferences apparent in 658 traditional folktales drawn from the ancient oral traditions of 48 different cultures (Gottschall et al., 2004). The analyses showed that the characters in these extremely old and diverse stories showed the same gender differences seen in contemporary research: Male characters tended to place a greater emphasis on potential mates' physical attractiveness, while female characters showed more interest in potential mates' wealth and social status.

There are some qualifications to these trends, but even these caveats make evolutionary sense. For example, when women are asked what they prefer in a *short-term partner* (for casual sex) they value physical attractiveness just as much as men (Li & Kenrick, 2006). And very attractive women, aware of their own high mate value, want it all—they want prospective male partners to exhibit excellent economic potential *and* physical attractiveness (Buss & Shackelford, 2008). Women's menstrual cycles also influence their mating preferences. When women are in mid-cycle approaching ovulation—that is, when they are most fertile—their preferences shift to favor men who exhibit masculine facial and bodily features, attractiveness, and dominance (Gangestad, Thornhill, & Garver-Apgar, 2005; Gangestad et al., 2007; Little et al., 2007). Men seem to recognize this shift, as they rate masculine males as more threatening when their partners are in the fertile portion of their menstrual cycle (Burriss & Little, 2006). Interestingly, although ovulation is far from obvious in human females, strippers earn more tip money per night when they are in their most fertile period (Miller, Tybur, & Jordan, 2007). Researchers aren't sure whether male patrons are "detecting" the strippers' heightened fertility or whether the ovulating dancers come on to the customers more because they are more sexually motivated.

The tactics used by people in pursuing their romantic relationships may include efforts at deception. Research shows that many men and women would be willing to lie about their personality, income, past relationships, and career skills to impress

ONE SECOND BEFORE THE BLIND DATE

do (Keenan et al., 1997). Perhaps this is the reason women tend to underestimate the strength of men's relationship commitment (Haselton & Buss, 2000). Men do not appear to show a similar bias, but they do show a tendency to overestimate women's sexual interest. These cognitive biases seem to be designed to reduce the probability that ancestral women would consent to sex and then be abandoned and to minimize the likelihood that ancestral men would overlook sexual opportunities (Buss, 2001).

Deception lies at the heart of *mate poaching,* a phenomenon that has recently attracted the interest of evolutionary psychologists. Mate poaching occurs when someone tries to attract another person who is already in a relationship. Although it presents some extra challenges and risks, this strategy is not rare, as 50%–60% of the undergraduate subjects in one study reported that they had attempted to poach someone (Schmitt & Buss, 2001). Mate poaching has probably occurred throughout history and is universally seen across cultures, although its prevalence varies some from one culture to another (Schmitt et al., 2003). Men are somewhat more likely than women to make poaching attempts, but the gap is modest and poaching by women is common (Schmitt et al., 2003). The tactics used in poaching efforts overlap considerably with the normal tactics of attraction, except the tactics are more likely to be executed in a disguised and secretive manner. Poaching is a two-way street, as people often try to entice others into poaching them by expressing boredom about their current relationship, complaining about their partner, or asking for "advice" about their relationship (Schmitt & Shackelford, 2003).

a prospective date who was attractive (Rowatt, Cunningham, & Druen, 1999). Consistent with evolutionary theory, women report that they are most upset when men exaggerate their social status, their financial resources, or the depth of their romantic commitment to the woman, whereas men are most upset when women conceal a history of "promiscuity" (Haselton et al., 2005). Females anticipate more deception from prospective dates than males

REVIEW of Key Learning Goals

16.8 People tend to like and love others who are physically attractive. The matching hypothesis asserts that people who are similar in physical attractiveness are more likely to be drawn together than those who are not. Byrne's research suggests that similarity causes attraction, although attitude alignment may also be at work.

16.9 Reciprocity involves liking those who show that they like you. In intimate relationships, how well a partner matches up with one's romantic ideals tends to influence the progress of the relationship. But comparisons to one's ideals are subjective, and romantic partners often idealize each other.

16.10 Berscheid and Hatfield distinguished between passionate love (complete absorption with sexual feelings) and companionate love (trusting, tolerant entwinement). Sternberg built on their distinction by dividing companionate love into intimacy (warmth, closeness, and sharing) and commitment (intent to maintain a relationship).

16.11 Hazan and Shaver's theory suggests that love relationships in adulthood mimic attachment patterns in infancy. People tend to fall into three attachment subtypes (secure, avoidant, or anxious-ambivalent) in their romantic relationships, although attachment style can also be viewed in terms of

how people score on two dimensions (attachment anxiety and avoidance). Those who are secure tend to have more committed, satisfying relationships. People high in attachment anxiety tend to have sex to reduce their insecurity and tend to have more difficulty than others with romantic breakups. Attachment style is related to many aspects of behavior.

16.12 The characteristics that people seek in prospective mates and gender differences in mating priorities are much the same around the world. However, cultures vary considerably in their emphasis on passionate love as a prerequisite for marriage. Although critics are concerned that Internet relationships are superficial and open to deception, Internet-initiated relationships appear to be just as intimate and stable as relationships forged offline.

16.13 According to evolutionary psychologists, certain aspects of good looks, such as facial symmetry and waist-to-hip ratio in women, influence attraction because they are indicators of reproductive fitness. Consistent with evolutionary theory, men tend to seek youthfulness and attractiveness in their mates, whereas women emphasize prospective mates' financial potential and willingness to invest material resources in children. People's courtship tactics may include deception. Females anticipate more deception than males do. Mate poaching is common and appears to be universal across cultures.

Attitudes: Making Social Judgments

In our chapter-opening story, Muffy's friends exhibited decidedly negative attitudes about working-class men. Their behavior reveals a basic feature of attitudes: they're evaluative. Social psychology's interest in attitudes has a much longer history than its interest in attraction. Indeed, in its early days social psychology was defined as the study of attitudes. In this section we'll discuss the nature of attitudes, efforts to change attitudes through persuasion, and theories of attitude change.

What are attitudes? *Attitudes* **are positive or negative evaluations of objects of thought.** "Objects of thought" may include social issues (capital punishment or gun control, for example), groups (liberals, farmers), institutions (the Lutheran church, the Supreme Court), consumer products (yogurt, computers), and people (the president, your next-door neighbor).

Components and Dimensions of Attitudes

Social psychologists have traditionally viewed attitudes as being made up of three components: a cognitive component, an affective component, and a behavioral component. However, it gradually became apparent that many attitudes do not include all three components (Fazio & Olson, 2003), so it is more accurate to say that *attitudes may include up to three components*. The *cognitive component* of an attitude is made up of the beliefs that people hold about the object of an attitude. The *affective component* of an attitude consists of the *emotional feelings* stimulated by an object of thought. The *behavioral component* of an attitude consists of *predispositions to act* in certain ways toward an attitude object. **Figure 16.8** provides concrete examples of how someone's attitude about gun control might be divided into its components.

Attitudes also vary along several crucial dimensions, including their *strength, accessibility,* and *ambivalence* (Olson & Maio, 2003). Definitions of *attitude strength* differ, but strong attitudes are generally seen as ones that are firmly held (resistant to change), that are durable over time, and that have a powerful impact on behavior (Petty, Wheeler, & Tormala, 2003). The *accessibility* of an attitude refers to how often one thinks about it and how quickly it comes to mind. Highly accessible attitudes are quickly and readily available (Fabrigar, MacDonald, & Wegener, 2005). Attitude accessibility is correlated with attitude strength, as highly accessible attitudes *tend* to be strong, but the concepts are distinct and there is no one-to-one correspondence. *Ambivalent attitudes* are conflicted evaluations that include both positive and negative feelings about an object of thought (Fabrigar et al., 2005). Like attitude

Attitude on gun control

Cognitive component (beliefs, ideas) — "Gun owners end up shooting themselves more often than they shoot thieves."

Affective component (emotions, feelings) — "Guns make me sick."

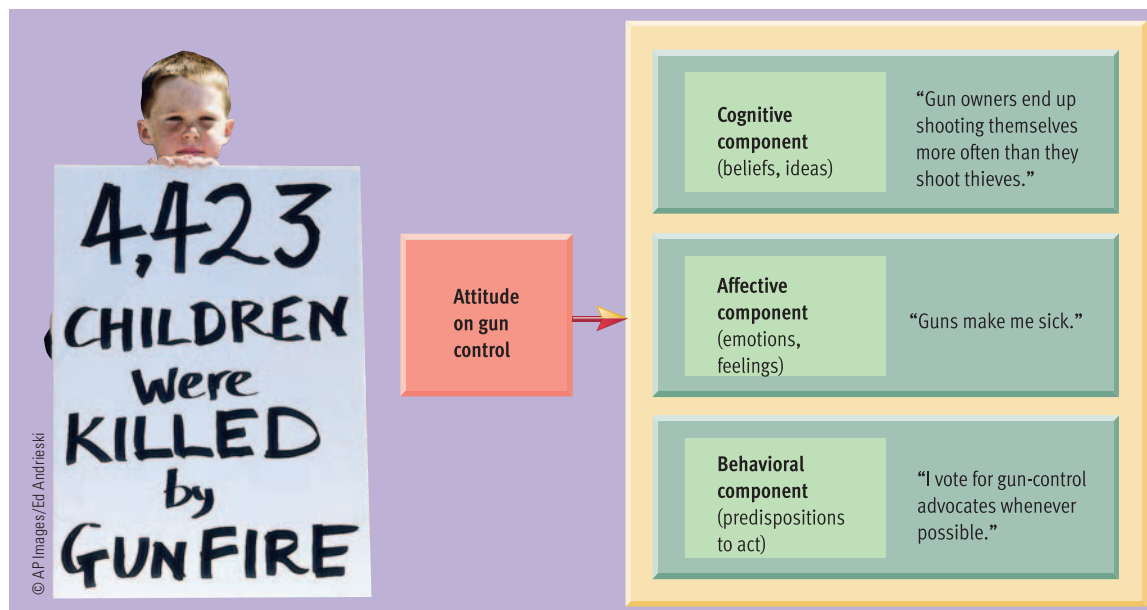
Behavioral component (predispositions to act) — "I vote for gun-control advocates whenever possible."


Figure 16.8

The possible components of attitudes. Attitudes may include cognitive, affective, and behavioral components, as illustrated here for a hypothetical person's attitude about gun control.

strength, attitude ambivalence has been measured in various ways (Priester & Petty, 2001). Generally speaking, ambivalence increases as the ratio of positive to negative evaluations gets closer to being equal. When ambivalence is high, an attitude tends to be less predictive of behavior and more pliable in the face of persuasion (Crano & Prislin, 2006).

Attitudes and Behavior

In the early 1930s, when prejudice against Asians was common in the United States, Richard LaPiere journeyed across the country with a Chinese couple. He was more than a little surprised when they weren't turned away from any of the restaurants they visited in their travels—184 restaurants in all. About six months after his trip, LaPiere surveyed the same restaurants and asked whether they would serve Chinese customers. Roughly half of the restaurants replied to the survey, and over 90% of them indicated that they would not seat Chinese patrons. Thus, LaPiere (1934) found that people who voice prejudicial attitudes may not behave in discriminatory ways. Since then, theorists have often asked: Why don't attitudes predict behavior better?

Admittedly, LaPiere's study had a fundamental flaw that you may already have detected. The person who seated LaPiere and his Chinese friends may not have been the same person who responded to the mail survey sent later. Nonetheless, numerous follow-up studies, using more sophisticated methods, have repeatedly shown that attitudes are mediocre predictors of people's behavior (Ajzen & Fishbein, 2005; Kraus, 1995). That's not to say that attitudes are irrelevant or meaningless. When Wallace and his colleagues (2005) reviewed 797 attitude-behavior studies, they found that the average correlation between attitudes and behavior was .41. That figure is high enough to justify Eagly's (1992) conclusion that researchers have identified "many conditions under which attitudes are substantial predictors of behavior" (p. 697). But on the whole, social psychologists have been surprised by how often a favorable attitude toward a candidate or product does not translate into a vote or a purchase.

Why aren't attitude-behavior relations more consistent? One consideration is that until recently researchers failed to take variations in *attitude strength, accessibility, and ambivalence* into account. Accumulating evidence indicates that these factors influence the connection between attitudes and behavior, but they have generally been left uncontrolled in decades of research on attitudes (Cooke & Sheeran, 2004; Olson & Maio, 2003). Research suggests that strong attitudes that are highly accessible and have been stable over time tend to be more predictive of behavior (Glasman & Albarracin, 2006). Another consideration is that attitudes are often measured in a *general, global* way that isn't likely to predict *specific* behaviors (Bohner & Schwarz, 2001). Although you may express favorable feelings about protecting civil liberties (a very general, abstract concept), you may not be willing to give $100 to the American Civil Liberties Union (a very specific action).

Finally, inconsistent relations between attitudes and behavior are seen because behavior depends on situational constraints—especially your subjective perceptions of how people expect you to behave (Ajzen & Fishbein, 2000, 2005). The review of research cited earlier (Wallace et al., 2005), which found that attitudes correlate .41 with behavior on average, also noted that when social pressures are high, this correlation diminishes to .30. Thus, attitudes interact with situational constraints to shape people's behavior. For instance, you may be strongly opposed to marijuana use but may not say anything when friends start passing a joint around at a party because you don't want to turn the party into an argument. However, in another situation governed by different norms, such as a class discussion, you may speak out forcefully against marijuana use. If so, you may be trying to change others' attitudes, the process we'll discuss next.

Trying to Change Attitudes: Factors in Persuasion

The fact that attitudes aren't always good predictors of a person's behavior doesn't stop others from trying to change those attitudes. Indeed, every day you're bombarded by efforts to alter your attitudes. To illustrate, let's trace the events of an imaginary morning. You may not even be out of bed before you start hearing radio advertisements intended to influence your attitudes about specific mouthwashes, computers, athletic shoes, and cell phones. If you check the news on your computer, you find not only more ads but quotes from government officials and special interest groups, carefully crafted to shape your opinions. When you arrive at school, you encounter a group passing out leaflets that urge you to repent your sins and join them in worship. In class, your economics professor champions the wisdom of free markets in international trade. At lunch, the person you've been dating argues about the merits of an "open relationship." Your discussion is interrupted by someone who wants both of you to sign a petition. "Doesn't it ever let up?" you wonder. When it comes to persuasion, the answer is "no." As Anthony Pratkanis and Elliot Aronson (2000) put it, we

live in the "age of propaganda." In light of this reality, let's examine some of the factors that determine whether persuasion works.

The process of persuasion includes four basic elements: source, receiver, message, and channel (see Figure 16.9). **The *source* is the person who sends a communication, and the *receiver* is the person to whom the message is sent.** Thus, if you watch a presidential news conference on TV, the president is the source, and you and millions of other viewers are the receivers. **The *message* is the information transmitted by the source, and the *channel* is the medium through which the message is sent.** Although the research on communication channels is interesting, we'll confine our discussion to source, message, and receiver variables.

Source Factors

Occasional exceptions to the general rule are seen, but persuasion tends to be more successful when the source has high *credibility* (Pornpitakpan, 2004). What gives a person credibility? Either expertise or trustworthiness. *Expertise* tends to be more influential when an argument is ambiguous or when the receiver is not motivated to pay close attention to the argument (Chaiken & Maheswaran, 1994; Reimer, Mata, & Stoecklin, 2004). People try to convey their expertise by mentioning their degrees, their training, and their experience or by showing an impressive grasp of the issue at hand.

Expertise is a plus, but *trustworthiness* can be even more important. Many people tend to accept messages from trustworthy sources with little scrutiny (Priester & Petty, 1995, 2003). If you were told that your state needs to reduce corporate taxes to stimulate its economy, would you be more likely to believe it from the president of a huge corporation in your state or from an economics professor from out of state? Probably the latter. Trustworthiness is undermined when a source, such as the corporation president, appears to have something to gain. In contrast, trustworthiness is enhanced when people appear to argue against their own interests (Hunt, Smith, & Kernan, 1985). This effect explains why salespeople often make remarks like, "Frankly, my snowblower isn't the best. They have a better brand down the street. Of course, you'll have to spend quite a bit more . . ."

Likability also increases the effectiveness of a persuasive source (Johnson, Maio, & Smith-McLallen, 2005), and some of the factors at work in attraction therefore have an impact on persuasion. Thus, the favorable effect of *physical attractiveness* on likability can make persuasion more effective (Reinhard, Messner, & Sporer, 2006). People also respond better to sources who are *similar* to them in ways that are relevant to the issue at hand (Hilmert, Kulik, & Christenfeld, 2006).

Message Factors

If you were going to give a speech to a local community group advocating a reduction in state taxes on corporations, you'd probably wrestle with a number of questions about how to structure your message. Should you look at both sides of the issue, or should you present just your side? Should you deliver a low-key, logical speech? Or should you try to strike fear into the hearts of your listeners? These questions are concerned with message factors in persuasion.

Let's assume that you're aware that there are two sides to the taxation issue. On the one hand, you're convinced that lower corporate taxes will bring new companies to your state and stimulate economic growth. On the other hand, you realize that reduced tax revenues may hurt the quality of education and roads in your state (but you think the benefits will outweigh the costs). Should you present a *one-sided argument* that ignores the possible problems for education and road quality? Or should you present a *two-sided argument* that acknowledges concern about education and road quality and then downplays the probable magnitude of these problems? The optimal strategy depends on a variety of considerations, but overall, two-sided arguments tend to be more effective (Petty & Wegener, 1998). Just mentioning that

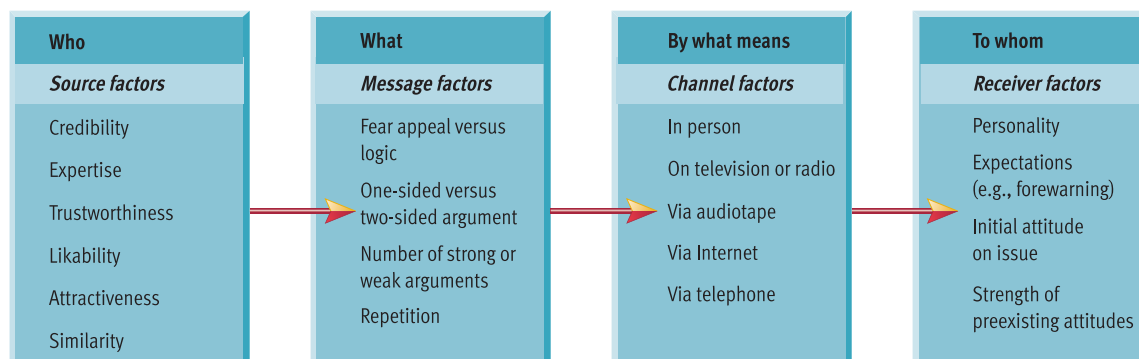
Who	What	By what means	To whom
Source factors	*Message factors*	*Channel factors*	*Receiver factors*
Credibility	Fear appeal versus logic	In person	Personality
Expertise	One-sided versus two-sided argument	On television or radio	Expectations (e.g., forewarning)
Trustworthiness	Number of strong or weak arguments	Via audiotape	Initial attitude on issue
Likability	Repetition	Via Internet	Strength of preexisting attitudes
Attractiveness		Via telephone	
Similarity			


Figure 16.9
Overview of the persuasion process. The process of persuasion essentially boils down to *who* (the source) communicates *what* (the message) *by what means* (the channel) *to whom* (the receiver). Thus, four sets of variables influence the process of persuasion: source, message, channel, and receiver factors. The diagram lists some of the more important factors in each category (including some that are not discussed in the text due to space limitations). (Adapted from Lippa, 1994)

there are two sides to an issue can increase your credibility with an audience.

Frequent repetition of a message also seems to be an effective strategy. The *validity effect* refers to the finding that simply repeating a statement causes it to be perceived as more valid or true. It doesn't matter whether the statement is true, false, or clearly just an opinion; if you repeat something often enough, some people come to believe it (Boehm, 1994; Weaver et al., 2007).

Persuasive messages frequently attempt to arouse fear. Opponents of nuclear power scare us with visions of meltdowns. Antismoking campaigns emphasize the threat of cancer, and deodorant ads highlight the risk of embarrassment. You could follow their lead and argue that if corporate taxes aren't reduced, your state will be headed toward economic ruin and massive unemployment. *Do appeals to fear work?* Yes—if they are successful in arousing fear. Research reveals that many messages intended to induce fear fail to do so. However, studies involving a wide range of issues (nuclear policy, auto safety, dental hygiene, and so on) have shown that messages that are effective in arousing fear tend to increase persuasion (Ruiter, Abraham, & Kok, 2001). Fear appeals are most likely to work when your listeners view the dire consequences that you describe as exceedingly unpleasant, fairly probable if they don't take your advice, and avoidable if they do (Das, de Wit, & Stroebe, 2003).

Receiver Factors

What about the receiver of the persuasive message? Are some people easier to persuade than others? Undoubtedly, but researchers have not found any personality traits that are reliably associated with susceptibility to persuasion (Petty & Wegener, 1998). Other factors, such as forewarning a receiver about a persuasive effort, generally seem to be more influential than the receiver's personality. An old saying suggests that "to be forewarned is to be forearmed." The value of *forewarning* applies to targets of persuasive efforts (Wood & Quinn, 2003). When you shop for a new TV, you *expect* salespeople to work at persuading you, and to some extent this forewarning reduces the impact of their arguments. Considerations that stimulate counterarguing in the receiver tend to increase resistance to persuasion (Jain, Buchanan, & Maheswaran, 2000).

Furthermore, studies show that *stronger attitudes are more resistant to change* (Eagly & Chaiken, 1998; Miller & Peterson, 2004). Strong attitudes may be tougher to alter because they tend to be embedded in networks of beliefs and values that might also require change (Erber, Hodges, & Wilson, 1995).

Finally, *resistance can promote resistance.* That is, when people successfully resist persuasive efforts to change specific attitudes, they often become more certain about those attitudes (Tormala & Petty, 2002, 2004).

Our review of source, message, and receiver variables has shown that attempting to change attitudes through persuasion involves a complex interplay of factors—and we haven't even looked beneath the surface yet. How do people acquire attitudes in the first place? What dynamic processes within people produce attitude change? We turn to these theoretical issues next.

Theories of Attitude Formation and Change

12c

Many theories have been proposed to explain the mechanisms at work in attitude change, whether or not it occurs in response to persuasion. We'll look at four theoretical perspectives: learning theory, dissonance theory, self-perception theory, and the elaboration likelihood model.

Learning Theory

12c

We've seen repeatedly that *learning theory* can help explain a wide range of phenomena, from conditioned fears to the acquisition of sex roles to the development of personality traits. Now we can add attitude formation and change to our list.

The affective, or emotional, component in an attitude can be created through a special subtype of *classical conditioning,* called evaluative conditioning (Olson & Fazio, 2001, 2002). As we discussed in Chapter 6, *evaluative conditioning* consists of efforts to transfer the emotion attached to a US to a new CS (Kruglanski & Stroebe, 2005; Schimmack & Crites, 2005). Advertisers routinely try to take advantage of evaluative conditioning by pairing their products with stimuli that elicit pleasant emotional responses, such as extremely attractive models, highly likable spokespersons, and cherished events, such as the Olympics (Till & Priluck, 2000). This conditioning process is diagrammed in **Figure 16.10**.

Operant conditioning may come into play when you openly express an attitude, such as "I believe that husbands should do more housework." Some people may endorse your view, while others may jump down your throat. Agreement from other people generally functions as a reinforcer, strengthening your tendency to express a specific attitude (Bohner & Schwarz, 2001). Disagreement often functions as a form of punishment, which may gradually weaken your commitment to your viewpoint.

Figure 16.10
Classical conditioning of attitudes in advertising. Advertisers routinely pair their products with likable celebrities in the hope that their products will come to elicit pleasant emotional responses. As discussed in Chapter 6, this special type of classical conditioning is called *evaluative conditioning.* See the Critical Thinking Application in Chapter 6 for a more in-depth discussion of this practice.

Understanding Attitudes and Persuasion

Check your understanding of the possible components of attitudes and the elements of persuasion by analyzing hypothetical political strategies. Imagine you're working on a political campaign and you're invited to join the candidate's inner circle in strategy sessions, as staff members prepare the candidate for upcoming campaign stops. During the meetings, you hear various strategies discussed. For each strategy below, indicate which component of voters' attitudes (cognitive, affective, or behavioral) is being targeted for change, and indicate which element in persuasion (source, message, or receiver factors) is being manipulated. The answers are in Appendix A.

1. "You need to convince this crowd that your program for regulating nursing homes is sound. Whatever you do, don't acknowledge the two weaknesses in the program that we've been playing down. I don't care if you're asked point blank. Just slide by the question and keep harping on the program's advantages."

   _____

2. "You haven't been smiling enough lately, especially when the TV cameras are rolling. Remember, you can have the best ideas in the world, but if you don't seem likable, you're not gonna get elected. By the way, I think I've lined up some photo opportunities that should help us create an image of sincerity and compassion."

   _____

3. "This crowd is already behind you. You don't have to alter their opinions on any issue. Get right to work convincing them to contribute to the campaign. I want them lining up to give money."

   _____

Another person's attitudes may rub off on you through *observational learning* (Oskamp, 1991). If you hear your uncle say, "Republicans are nothing but puppets of big business" and your mother heartily agrees, your exposure to your uncle's attitude and your mother's reinforcement of your uncle may influence your attitude toward the Republican party. Studies show that parents and their children tend to have similar political attitudes (Sears, 1975) and that college students living in residence halls tend to show some convergence in attitudes (Cullum & Harton, 2007). Observational learning may account for much of this similarity. The opinions of teachers, coaches, co-workers, talk-show hosts, rock stars, and so forth are also likely to sway people's attitudes through observational learning.

Dissonance Theory   12c

Leon Festinger's *dissonance theory* assumes that inconsistency among attitudes propels people in the direction of attitude change. Dissonance theory burst into prominence in 1959 when Festinger and J. Merrill Carlsmith published a famous study of counterattitudinal behavior. Let's look at their findings and at how dissonance theory explains them.

Festinger and Carlsmith (1959) had male college students come to a laboratory, where they worked on excruciatingly dull tasks such as turning pegs repeatedly. When a subject's hour was over, the experimenter confided that some participants' motivation was being manipulated by telling them that the task was interesting and enjoyable before they started it. Then, after a moment's hesitation, the experimenter asked if the subject could help him out of a jam. His usual helper was delayed and he needed someone to testify to the next "subject" (really an accomplice) that the experimental task was interesting. He offered to pay the subject if he would tell the person in the adjoining waiting room that the task was enjoyable and involving.

This entire scenario was enacted to coax participants into doing something that was inconsistent with their true feelings—that is, to engage in *counterattitudinal behavior.* Some participants received a token payment of $1 for their effort, while others received a more substantial payment of $20 (an amount equivalent to about $80–$90 today, in light of inflation). Later, a second experimenter inquired about the subjects' true feelings regarding the dull
Leon Festinger

"Cognitive dissonance is a motivating state of affairs. Just as hunger impels a person to eat, so does dissonance impel a person to change his opinions or his behavior."

Hypothesis:
High dissonance about counterattitudinal behavior will cause attitude change

Random assignment

Subjects randomly assigned to experimental and control groups

Manipulation of independent variable

Experimental group
Subjects paid $1 for saying task is fun (high dissonance)

Control group
Subjects paid $20 for saying task is fun (low dissonance)

Measurement of dependent variable

Dull task is rated more enjoyable by the high-dissonance subjects

Conclusion:
Dissonance about counterattitudinal behavior does cause attitude change

Figure 16.11

Design of the Festinger and Carlsmith (1959) study. The sequence of events in this landmark study of counterattitudinal behavior and attitude change is outlined here. The diagram omits a third condition (no dissonance), in which subjects were not induced to lie. The results in the nondissonance condition were similar to those found in the low-dissonance condition.

experimental task. **Figure 16.11** summarizes the design of the Festinger and Carlsmith study.

Who do you think rated the task more favorably—the subjects who were paid $1 or those who were paid $20? Both common sense and learning theory would predict that the subjects who received the greater reward ($20) should come to like the task more. In reality, however, the subjects who were paid $1 exhibited more favorable attitude change—just as Festinger and Carlsmith had predicted. Why? Dissonance theory provides an explanation.

According to Festinger (1957), *cognitive dissonance* **exists when related cognitions are inconsistent—that is, when they contradict each other.** Cognitive dissonance is thought to create an unpleasant state of tension that motivates people to reduce their dissonance—usually by altering their cognitions. In the study by Festinger and Carlsmith, the subjects' contradictory cognitions were "The task is boring" and "I told someone the task was enjoyable." The subjects who were paid $20 for lying had an obvious reason for behaving inconsistently with their true attitudes, so these subjects experienced little dissonance. In contrast, the subjects paid $1 had no readily apparent justification for their lie and experienced high dissonance. To re-

duce it, they tended to persuade themselves that the task was more enjoyable than they had originally thought. Thus, dissonance theory sheds light on why people sometimes come to believe their own lies.

Cognitive dissonance is also at work when people turn attitudinal somersaults to justify efforts that haven't panned out, a syndrome called *effort justification.* Aronson and Mills (1959) studied effort justification by putting college women through a "severe initiation" before they could qualify to participate in what promised to be an interesting discussion of sexuality. In the initiation, the women had to read obscene passages out loud to a male experimenter. After all that, the highly touted discussion of sexuality turned out to be a boring, taped lecture on reproduction in lower animals. Subjects in the severe initiation condition experienced highly dissonant cognitions ("I went through a lot to get here" and "This discussion is terrible"). How did they reduce their dissonance? Apparently by changing their attitude about the discussion, since they rated it more favorably than subjects in two control conditions. Effort justification may be at work in many facets of everyday life. For example, people who wait in line for an hour or more to get into an exclusive restaurant often praise the restaurant afterward even if they have been served a mediocre meal.

Dissonance theory has been tested in hundreds of studies with mixed, but largely favorable, results. The dynamics of dissonance appear to underlie many important types of attitude changes (Draycott & Dabbs, 1998; Keller & Block, 1999; Petty et al., 2003). Research has largely supported Festinger's claim that dissonance involves genuine psychological discomfort and even physiological arousal (Visser & Cooper, 2003; Devine et al., 1999). However, dissonance effects are not among the most reliable phenomena in social psychology. Researchers have had difficulty specifying the conditions under which dissonance will occur, and it has become apparent that people can reduce their dissonance in quite a variety of ways besides changing their attitudes (Olson & Stone, 2005; Visser & Cooper, 2003).

PSYK TREK

Self-Perception Theory   **12c**

After taking a close look at studies of counterattitudinal behavior, Daryl Bem (1967) concluded that self-perception, rather than dissonance, explains why people sometimes come to believe their own lies. According to Bem's *self-perception theory,* people often *infer* their attitudes from their behavior. Thus, Bem argued that in the study by Festinger and Carlsmith (1959), the subjects paid $1 probably thought

to themselves, "A dollar isn't enough money to get me to lie, so I must have found the task enjoyable."

This thinking isn't much different from what dissonance theory would predict. Both theories suggest that people often think, "If I said it, it must be true." But the two theories propose that similar patterns of thought unfold for entirely different reasons. According to dissonance theory, subjects think along these lines because they're struggling to reduce tension caused by inconsistency among their cognitions. According to self-perception theory, subjects are engaged in normal attributional efforts to better understand their own behavior. Bem originally believed that most findings explained by dissonance were really due to self-perception. However, studies eventually showed that self-perception is at work primarily when subjects do not have well-defined attitudes regarding the issue at hand (Olson & Roese, 1995). Although self-perception theory did not replace dissonance theory, Bem's work demonstrated that attitudes are sometimes inferred from one's own behavior (Olson & Stone, 2005; see **Figure 16.12**).

Elaboration Likelihood Model   12c

The *elaboration likelihood model* of attitude change, originally proposed by Richard Petty and John Cacioppo (1986), asserts that there are two basic "routes" to persuasion (Petty & Brinol, 2008; Petty & Wegener, 1999). The *central route* is taken when people carefully ponder the content and logic of persuasive messages. The *peripheral route* is taken when persuasion depends on nonmessage factors, such as the attractiveness and credibility of the source, or on conditioned emotional responses (see **Figure 16.13**). For example, a politician who campaigns by delivering carefully researched speeches that thoughtfully analyze complex issues is following the central route to persuasion. In contrast, a politician who depends on marching bands, flag waving, celebrity endorsements, and emotional slogans is following the peripheral route.

Both routes can lead to persuasion. However, according to the elaboration likelihood model, the durability of attitude change depends on the extent to which people elaborate on (think about) the contents of persuasive communications. Studies suggest that the central route to persuasion leads to more enduring attitude change than the peripheral route and that attitudes changed through central processes predict behavior better than attitudes changed through peripheral processes (Kruglanski & Stroebe, 2005; Petty & Wegener, 1998).

Traditional view
Attitudes determine behavior

Attitude
"I don't like liberal politicians."

Behavior
"I vote only for conservatives."

Bem's self-perception theory
Behavior determines attitudes

Behavior
"Now that I think about it, I vote only for conservatives."

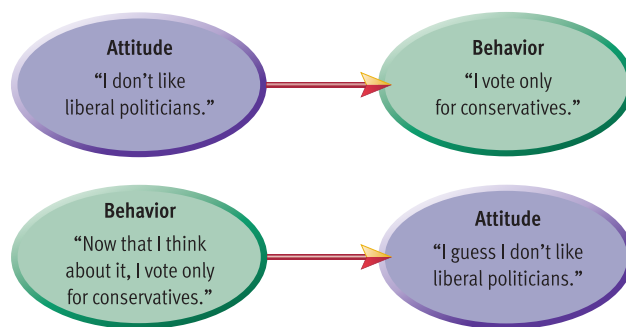
Attitude
"I guess I don't like liberal politicians."


Figure 16.12
Bem's self-perception theory. The traditional view is that attitudes determine behavior. However, Bem stood conventional logic on its head when he proposed that behavior often determines (or causes people to draw inferences about) their attitudes. Subsequent research on attribution has shown that sometimes people *do* infer their attitudes from their behavior.

REVIEW of Key Learning Goals

16.14 Attitudes may be made up of cognitive, affective, and behavioral components. Attitudes vary along the dimensions of strength, accessibility, and ambivalence. Attitudes and behavior aren't as consistent as one might assume, for a variety of reasons, including the need to consider situational pressures.

16.15 A source of persuasion who is credible, expert, trustworthy, likable, and physically attractive tends to be relatively effective in stimulating attitude change. Although there are some situational limitations, two-sided arguments and fear arousal are effective elements in persuasive messages. Repetition of a message is also helpful. Persuasion is more difficult when a receiver is forewarned and when strong attitudes are targeted.

16.16 Attitudes may be shaped through classical conditioning, operant conditioning, and observational learning. Festinger's dissonance theory asserts that inconsistent attitudes cause tension and that people alter their attitudes to reduce cognitive dissonance. Dissonance theory has been used to explain attitude change following counterattitudinal behavior and efforts that haven't panned out.

16.17 Self-perception theory proposes that people sometimes infer their attitudes from their behavior. The elaboration likelihood model holds that the central route to persuasion, which depends on the logic of persuasive messages, tends to yield longer-lasting attitude change than the peripheral route, which depends on nonmessage factors.

Central route
Persuasion based on content and logic of the message → **High elaboration:** Careful processing of the information → More durable attitude change

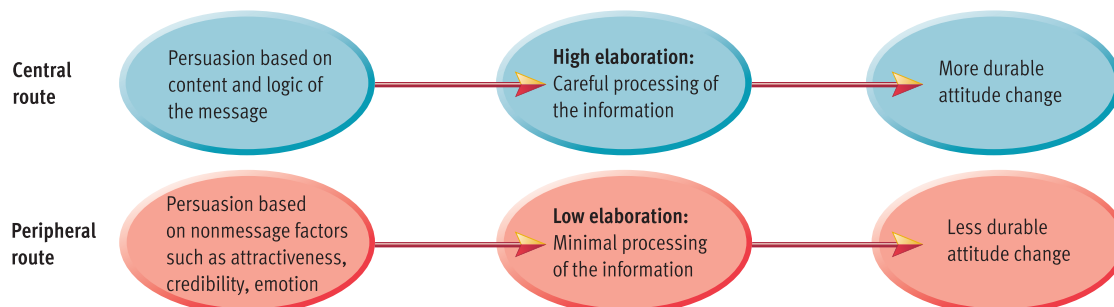
Peripheral route
Persuasion based on nonmessage factors such as attractiveness, credibility, emotion → **Low elaboration:** Minimal processing of the information → Less durable attitude change


Figure 16.13
The elaboration likelihood model. According to the elaboration likelihood model (Petty & Cacioppo, 1986), the central route to persuasion leads to more elaboration of message content and more enduring attitude change than the peripheral route to persuasion.

Conformity and Obedience: Yielding to Others

A number of years ago, the area that I lived in experienced a severe flood that required the mobilization of the National Guard and various emergency services. At the height of the crisis, a young man arrived at the scene of the flood, announced that he was from an obscure state agency that no one had ever heard of, and proceeded to take control of the emergency. City work crews, the fire department, local police, municipal officials, and the National Guard followed his orders with dispatch for several days, evacuating entire neighborhoods—until an official thought to check and found out that the man was just someone who had walked in off the street. The imposter, who had had small armies at his beck and call for several days, had no training in emergency services, just a history of unemployment and psychological problems.

After news of the hoax spread, people criticized red-faced local officials for their compliance with the imposter's orders. However, many of the critics probably would have cooperated in much the same way if they had been in the officials' shoes. For most people, willingness to obey someone in authority is the rule, not the exception. In this section, we'll analyze the dynamics of social influence at work in conformity and obedience.

Conformity

12e

If you keep a well-manicured lawn, are you exhibiting conformity? According to social psychologists, it depends on whether your behavior is the result of group pressure. *Conformity* **occurs when people yield to real or imagined social pressure**. For example, if you maintain a well-groomed lawn only to avoid complaints from your neighbors, you're conforming to social pressure. However, if you maintain a nice lawn because you genuinely prefer a nice lawn, that's *not* conformity.

In the 1950s, Solomon Asch (1951, 1955, 1956) devised a clever procedure that reduced ambiguity about whether subjects were conforming, allowing him to investigate the variables that govern conformity. Let's re-create one of Asch's (1955) classic experiments, which have become the most widely replicated studies in the history of social psychology (Markus, Kitayama, & Heiman, 1996). The participants are male undergraduates recruited for a study of visual perception. A group of seven subjects are shown a large card with a vertical line on it and

are then asked to indicate which of three lines on a second card matches the original "standard line" in length (see **Figure 16.14**). All seven subjects are given a turn at the task, and they announce their choice to the group. The subject in the sixth chair doesn't know it, but everyone else in the group is an accomplice of the experimenter, and they're about to make him wonder whether he has taken leave of his senses.

The accomplices give accurate responses on the first two trials. On the third trial, line number 2 clearly is the correct response, but the first five "subjects" all say that line number 3 matches the standard line. The genuine subject is bewildered and can't believe his ears. Over the course of the next 15 trials, the accomplices all give the same incorrect response on 11 of them. How does the real subject respond? The line judgments are easy and unambiguous. So, if the participant consistently agrees with the accomplices, he isn't making honest mistakes—he's conforming.

Averaging across all 50 participants, Asch (1955) found that the young men conformed on 37% of the trials. The subjects varied considerably in their tendency to conform, however. Of the 50 participants, 13 never caved in to the group, while 14 conformed on more than half the trials. One could argue that the results show that people confronting a unanimous majority generally tend to *resist* the pressure to conform, but given how clear and easy the line judgments were, most social scientists viewed the findings as a dramatic demonstration of humans' propensity to conform (Levine, 1999).

Text not available due to copyright restrictions

Solomon Asch

"That we have found the tendency to conformity in our society so strong that reasonably intelligent and well-meaning young people are willing to call white black is a matter of concern."

In subsequent studies, Asch (1956) found that *group size* and *group unanimity* are key determinants of conformity. To examine the impact of group size, Asch repeated his procedure with groups that included from 1 to 15 accomplices. Little conformity was seen when a subject was pitted against just one person, but conformity increased as group size went up to 4, and then leveled off (see **Figure 16.15**). Thus, Asch reasoned that as groups grow larger, conformity increases—up to a point, a conclusion that has been echoed by other researchers (Cialdini & Trost, 1998).

However, group size made little difference if just one accomplice "broke" with the others, wrecking their unanimous agreement. The presence of another dissenter lowered conformity to about one-quarter of its peak, even when the dissenter made *inaccurate* judgments that happened to conflict with the majority view. Apparently, the participants just needed to hear someone else question the accuracy of the group's perplexing responses. The importance of unanimity in fostering conformity has been replicated in subsequent research (Nemeth & Chiles, 1988).

Obedience   12e

Obedience is a form of compliance that occurs when people follow direct commands, usually from someone in a position of authority. To a surprising extent, when an authority figure says, "Jump!" many people simply ask, "How high?"

Milgram's Studies   12e

Stanley Milgram wanted to study this tendency to obey authority figures. Like many other people after World War II, he was troubled by how readily the citizens of Germany had followed the orders of dic-

Text not available due to copyright restrictions

tator Adolf Hitler, even when the orders required morally repugnant actions, such as the slaughter of millions of Jews. Milgram, who had worked with Solomon Asch, set out to design a standard laboratory procedure for the study of obedience, much like Asch's procedure for studying conformity. The clever experiment that Milgram devised became one of the most famous and controversial studies in the annals of psychology. It has been hailed as a "monumental contribution" to science and condemned as "dangerous, dehumanizing, and unethical research" (Ross, 1988). Because of its importance, it's our Featured Study for this chapter.

"I Was Just Following Orders"

"I was just following orders." That was the essence of Adolf Eichmann's defense when he was tried for his war crimes, which included masterminding the Nazis' attempted extermination of European Jews. Milgram wanted to determine the extent to which people are willing to follow authorities' orders. In particular, he wanted to identify the factors that lead people to follow commands that violate their ethics, such as commands to harm an innocent stranger.

Method

The participants were a diverse collection of 40 men from the local community, recruited through advertisements to participate in a study at Yale University. When a subject arrived at the lab, he met the experimenter and another sub-

ject, a likable, 47-year-old accountant, who was actually an accomplice of the experimenter. The "subjects" were told that the study would concern the effects of punishment on learning. They drew slips of paper from a hat to get their assignments, but the drawing was fixed so that the real subject always became the "teacher" and the accomplice the "learner."

The participant then watched as the learner was strapped into an electrified chair through which a shock could be delivered to the learner whenever he made a mistake on the task (left photo in **Figure 16.16** on the next page). The subject was told that the shocks would be painful but "would not cause tissue damage," and he was then taken to an adjoining room that housed the shock

Level of shock (as labeled on Milgram's shock machine)

Stanley Milgram

"*The essence of obedience is that a person comes to view himself as the instrument for carrying out another person's wishes, and he therefore no longer regards himself as responsible for his actions.*"

generator that he would control in his role as the teacher. This elaborate apparatus (right photo in **Figure 16.16**) had 30 switches designed to administer shocks varying from 15 to 450 volts, with labels ranging from "Slight shock" to "Danger: severe shock" and "XXX." Although the apparatus looked and sounded realistic, it was a fake, and the learner was never shocked.

As the "learning experiment" proceeded, the accomplice made many mistakes that necessitated shocks from the teacher, who was instructed to increase the shock level after each wrong answer. At "300 volts," the learner began to pound on the wall between the two rooms in protest and soon stopped responding to the teacher's questions. At this point, participants ordinarily turned to the experimenter for guidance. The experimenter, a 31-year-old male in a gray lab coat, firmly indicated that no response was the same as a wrong answer and that the teacher should continue to give stronger and stronger shocks to the now silent learner. If the participant expressed unwillingness to continue, the experimenter responded sternly with one of four pre-arranged prods, such as, "It is absolutely essential that you continue."

When a participant refused to obey the experimenter, the session came to an end. The dependent variable was the maximum shock the participant was willing to administer before refusing to cooperate. After each session, the true purpose of the study was explained to the subject, who was reassured that the shock was fake and the learner was unharmed.

Results

No participant stopped cooperating before the learner reached the point of pounding on the wall, but 5 quit at that point. As the graph in **Figure 16.16** shows, only 14

out of 40 subjects defied the experimenter before the full series of shocks was completed. Thus, 26 of the 40 subjects (65%) administered all 30 levels of shock. Although they tended to obey the experimenter, many participants voiced and displayed considerable distress about harming the learner. The horrified subjects groaned, bit their lips, stuttered, trembled, and broke into a sweat, but they continued administering the shocks.

Discussion

Based on these results, Milgram concluded that obedience to authority is even more common than he or others had anticipated. Before the study was conducted, Milgram had described it to 40 psychiatrists and had asked them to predict how much shock subjects would be willing to administer to their innocent victims. Most of the psychiatrists had predicted that fewer than 1% of the subjects would continue to the end of the series of shocks!

In interpreting his results, Milgram argued that strong pressure from an authority figure can make decent people do indecent things to others. Applying this insight to Nazi war crimes and other travesties, Milgram asserted that some sinister actions may not be due to actors' evil character so much as to situational pressures that can lead normal people to engage in acts of treachery and violence. Thus, he arrived at the disturbing conclusion that given the right circumstances, anyone might obey orders to inflict harm on innocent strangers.

Comment

In itself, obedience is not necessarily bad or wrong. Social groups of any size depend on obedience to function smoothly. Life would be chaotic if orders from police, parents, physicians, bosses, generals, and presidents were

routinely ignored. However, Milgram's study suggests that many people are overly willing to submit to the orders of someone in command.

If you're like most people, you're probably confident that you wouldn't follow an experimenter's demands to inflict harm on a helpless victim. But the empirical findings indicate that you're probably wrong. After many replications, the results are deplorable, but clear: Most people can be coerced into engaging in actions that violate their morals and values. This finding is disheartening, but it sharpens our understanding of moral atrocities, such as the Nazi persecutions of Jews.

After his initial demonstration, Milgram (1974) tried about 20 variations on his experimental procedure, looking for factors that influence participants' obedience. In one variation, Milgram moved the study away from Yale's campus to see if the prestige of the university was contributing to the subjects' obedience. When the study was run in a seedy office building by the "Research Associates of Bridgeport," only a small decrease in obedience was observed (48% of the subjects gave all the shocks).

In another version of the study, Milgram borrowed a trick from Asch's conformity experiments and set up teams of three teachers that included two more accomplices. When they drew lots, the real subject was always selected to run the shock apparatus in consultation with his fellow teachers. When both accomplices accepted the experimenter's orders to continue shocking the learner, the pressure increased obedience a bit. However, if an accomplice defied the experimenter and supported the subject's objections, obedience declined dramatically (only 10% of the subjects gave all the shocks), just as conformity had dropped rapidly when dissent surfaced in Asch's conformity studies. Dissent from another "teacher" turned out to be one of the few variations that reduced participants' obedience appreciably. As a whole, Milgram was surprised at how high subjects' obedience remained as he changed various aspects of his experiment.

The Ensuing Controversy   12e

Milgram's study evoked a controversy that continues through today. Some critics argued that Milgram's results couldn't be generalized to apply to the real world (Baumrind, 1964; Orne & Holland, 1968). They maintained that participants went along only because they knew it was an experiment and "everything must be okay." Or they argued that subjects who agree to participate in a scientific study *expect to obey* orders from an experimenter. Milgram (1964, 1968) replied by arguing that if subjects had thought "everything must be okay," they wouldn't have experienced the enormous distress that they clearly showed.

As for the idea that research participants expect to follow an experimenter's commands, Milgram pointed out that so do real-world soldiers and bureaucrats who are accused of villainous acts performed in obedience to authority. "I reject Baumrind's argument that the observed obedience doesn't count because it occurred where it is appropriate," said Milgram (1964). "That is precisely why it *does* count." Overall, the evidence supports the generalizability of Milgram's results, which were consistently replicated for many years, in diverse settings, with a variety of subjects and procedural variations (Blass, 1999; Miller, 1986).

Critics also questioned the ethics of Milgram's procedure (Baumrind, 1964; Kelman, 1967). They noted that without prior consent, subjects were exposed to extensive deception that could undermine their trust in people and to severe stress that could leave emotional scars. Moreover, most participants also had to confront the disturbing fact that they caved in to the experimenter's commands to inflict harm on an innocent victim.

Milgram's defenders argued that the brief distress experienced by his participants was a small price to pay for the insights that emerged from his obedience studies. Looking back, however, many psychologists seem to share the critics' concerns about the ethical implications of Milgram's work. His procedure is questionable by contemporary standards of research ethics, and no exact replications of his obedience study have been conducted in the United States since the mid-1970s (Blass, 1991)—a bizarre epitaph for what may be psychology's best-known experiment.

Cultural Variations in Conformity and Obedience

Are conformity and obedience unique to American culture? By no means. The Asch and Milgram experiments have been repeated in many societies, where they have yielded results roughly similar to those seen in the United States. Thus, the phenomena of conformity and obedience seem to transcend culture.

The replications of Milgram's obedience study have largely been limited to industrialized nations similar to the United States. Comparisons of the

results of these studies must be made with caution because the composition of the samples and the experimental procedures have varied somewhat. But many of the studies have reported even higher obedience rates than those seen in Milgram's American samples. For example, obedience rates of over 80% have been reported for samples from Italy, Germany, Austria, Spain, and Holland (Smith & Bond, 1994). Thus, the surprisingly high level of obedience observed by Milgram does not appear to be peculiar to the United States.

The Asch experiment has been repeated in a more diverse range of societies than the Milgram experiment. Like many other cultural differences in social behavior, variations in conformity appear to be related to the degree of *individualism versus collectivism* seen in a society. Various theorists have argued that collectivistic cultures, which emphasize respect for group norms, cooperation, and harmony, probably encourage more conformity than individualistic cultures (Schwartz, 1990) and have a more positive view of conformity (Kim & Markus, 1999). As Matsumoto (1994) puts it, "To conform in American culture is to be weak or deficient somehow. But this is not true in other cultures. Many cultures foster more collective, group-oriented values, and concepts of conformity, obedience, and compliance enjoy much higher status" (p. 162). Consistent with this analysis, studies *have* found higher levels of conformity in collectivistic cultures than in individualistic cultures (Bond & Smith, 1996; Smith, 2001).

The Power of the Situation: The Stanford Prison Simulation

The research of Asch and Milgram provided dramatic demonstrations of the potent influence that situational factors can have on social behavior. The power of the situation was underscored once again, about a decade after Milgram's obedience research, in another landmark study conducted by Philip Zimbardo, who, ironically, was a high school classmate of Milgram's. Zimbardo and his colleagues designed the Stanford Prison Simulation to investigate why prisons tend to become abusive, degrading, violent environments (Haney, Banks, & Zimbardo, 1973; Zimbardo, Haney, & Banks, 1973). Like Milgram, Zimbardo wanted to see how much the power of the situation would shape the behavior of normal, average subjects.

The participants were college students recruited for a study of prison life through a newspaper ad. After giving 70 volunteers an extensive battery of tests and interviews, the researchers chose 24 students who appeared to be physically healthy and psychologically stable to be the subjects. A coin flip

Philip Zimbardo

"But in the end, I called off the experiment not because of the horror I saw out there in the prison yard, but because of the horror of realizing that I could have easily traded places with the most brutal guard or become the weakest prisoner full of hatred at being so powerless."

determined which of them would be "guards" and which would be "prisoners" in a simulated prison setup at Stanford University. The prisoners were "arrested" at their homes, handcuffed, and transported to a mock prison on the Stanford campus. Upon arrival, they were ordered to strip, sprayed with a delousing agent, given prison uniforms (smocks), assigned numbers as their identities, and locked up in iron-barred cells. The subjects assigned to be guards were given khaki uniforms, billy clubs, whistles, and reflective sunglasses. They were told that they could run their prison in whatever way they wanted except that they were not allowed to use physical punishment.

What happened? In short order, confrontations occurred between the guards and prisoners, and the guards quickly devised a variety of sometimes cruel strategies to maintain total control over their prisoners. Meals, blankets, and bathroom privileges were selectively denied to some prisoners to achieve control. The prisoners were taunted, humiliated, called demeaning names, and forced to beg for opportunities to go to the bathroom. Pointless, petty rules were strictly enforced and difficult prisoners were punished with hard labor (doing pushups and jumping jacks, cleaning toilets with their bare hands). The guards harassed the prisoners by waking them up in the middle of the night to assemble and count off. And the guards creatively turned a 2-foot by 2-foot closet into a "hole" for solitary confinement of rebellious prisoners. Although there was some variation among the guards, collectively they became mean, malicious, and abusive in fulfilling their responsibilities. How did the prisoners react? A few showed signs of emotional disturbance and had to be released early, but they mostly became listless, apathetic, and demoralized. The study was designed to run two weeks, but Zimbardo decided that he needed to end it prematurely after just six days because he was concerned about the rapidly escalating abuse and degradation of the prisoners. The subjects were debriefed, offered counseling, and sent home.

How did Zimbardo and his colleagues explain the stunning transformations of their subjects? First, they attributed the participants' behavior to the enormous influence of social roles. ***Social roles* are widely shared expectations about how people in certain positions are supposed to behave.** We have role expectations for salespeople, waiters, ministers, medical patients, students, bus drivers, tourists, flight attendants, and, of course, prison guards and prisoners. The participants had a rough idea of what it meant to act like a guard or a prisoner and they were gradually consumed by their roles (Haney & Zimbardo, 1998). Second, the researchers attributed

The recent Abu Ghraib prison scandal in Iraq has sparked renewed interest in the Stanford Prison Simulation. Some of the photos taken of the abuse at Abu Ghraib (right) are stunningly similar to photos from the Stanford study (left). For instance, in both cases, the guards "dehumanized" their prisoners by placing bags over their heads.

their subjects' behavior to the compelling power of situational factors. Before the study began, the tests and interviews showed no measureable differences in personality or character between those randomly assigned to be guards versus prisoners. The stark differences in their behavior had to be due to the radically different situations that they found themselves in. As Haney and Zimbardo (1998, p. 719) put it, the study "demonstrated the power of situations to overwhelm people and elicit from them unexpectedly cruel, yet 'situationally appropriate' behavior." As a result, Zimbardo, like Milgram before him, concluded that situational pressures can lead normal, decent people to behave in sinister, repugnant ways.

The results of the Stanford Prison Simulation were eye-opening, to say the least. Within a short time, subjects with no obvious character flaws became tyrannical, sadistic, brutal guards. If this transformation can occur so swiftly in a make-believe prison, one can only imagine how the much stronger situational forces in real prisons readily promote abusive behavior. Although the Stanford Prison Simulation was conducted over 30 years ago, renewed interest in the study was sparked by the Abu Ghraib prison scandal in Iraq in 2004. American military personnel with little or no experience in running prisons were found to have engaged in "sadistic, blatant, and wanton criminal abuses" of their Iraqi prisoners (Hersh, 2004). Some of the photos taken of the abuse at Abu Ghraib are eerily reminiscent of photos from the Stanford simulation. The U.S. government blamed these horrific abuses on "a few bad apples" who were presumed to be pathological or morally deficient, writing off the incident as an aberration. Yet the evidence from the Stanford Prison Simulation clearly suggests otherwise. Phil Zimbardo (2004,

2007) argues, and has testified as an expert witness, that it is far more likely that situational pressures led normal, average Americans to commit morally reprehensible abuses. This explanation does *not* absolve the brutal guards of responsibility for their behavior. However, Zimbardo emphasizes that making scapegoats out of a handful of guards does not solve the real problem, which lies in the system. He maintains that abuses in prisons are more likely than not and can only be reduced if authorities provide extensive training and strong supervision for guards, enact explicit sanctions for abuses, and maintain clear accountability in the chain of command.

REVIEW of Key Learning Goals

16.18 Asch found that subjects often conform to the group, even when the group reports inaccurate judgments on a simple line-judging task. Conformity becomes more likely as group size increases, up to a group size of four, then levels off. If a small group isn't unanimous, conformity declines rapidly.

16.19 In Milgram's landmark study of obedience to authority, adult men drawn from the community showed a remarkable tendency, despite their misgivings, to follow orders to shock an innocent stranger. Milgram concluded that situational pressures can make decent people do indecent things. Critics asserted that Milgram's results were not generalizable to the real world and that his methods were unethical. The generalizability of Milgram's findings has stood the test of time, but his work also helped to stimulate stricter ethical standards for research.

16.20 The Asch and Milgram experiments have been replicated in many cultures. These replications have uncovered modest cultural variations in the propensity to conform or to obey an authority figure.

16.21 The Stanford Prison Simulation, in which normal, healthy students were randomly assigned to be prisoners or guards, demonstrated that social roles and other situational pressures can exert tremendous influence over social behavior. Like Milgram, Zimbardo showed that situational forces can lead normal people to exhibit surprisingly callous, abusive behavior.

Social psychologists study groups as well as individuals, but exactly what is a group? Are all the divorced fathers living in Baltimore a group? Are three strangers moving skyward in an elevator a group? What if the elevator gets stuck? How about four students from your psychology class who study together regularly? A jury deciding a trial? The Boston Celtics? The U.S. Congress? Some of these collections of people are groups and others aren't. Let's examine the concept of a group to find out which of these collections qualify.

In social psychologists' eyes, **a *group* consists of two or more individuals who interact and are interdependent.** The divorced fathers in Baltimore aren't likely to qualify on either count. Strangers sharing an elevator might interact briefly, but they're not interdependent. However, if the elevator got stuck and they had to deal with an emergency together, they could suddenly become a group. Your psychology classmates who study together are a group, as they interact and depend on each other to achieve shared goals. So do the members of a jury, a sports team such as the Celtics, and a large organization such as the U.S. Congress. Historically, most groups have interacted on a face-to-face basis, but advances in telecommunications are changing that reality. In the era of the Internet, people can interact, become interdependent, and develop a group identity without ever meeting in person (Bargh & McKenna, 2004; McKenna & Bargh, 1998).

Groups vary in many ways. Obviously, a study group, the Celtics, and Congress are very different in terms of size, purpose, formality, longevity, similarity of members, and diversity of activities. Can anything meaningful be said about groups if they're so diverse? Yes. In spite of their immense variability, groups share certain features that affect their functioning. Among other things, most groups have *roles* that allocate special responsibilities to some members, *norms* about suitable behavior, a *communication structure* that reflects who talks to whom, and a *power structure* that determines which members wield the most influence (Forsyth, 2006).

Thus, when people join together in a group, they create a social organism with unique characteristics and dynamics that can take on a life of its own. One of social psychology's enduring insights is that in a given situation you may behave quite differently when you're in a group than when you're alone. To illustrate this point, let's look at some interesting research on helping behavior.

Behavior Alone and in Groups: The Case of the Bystander Effect

Imagine that you have a precarious medical condition and that you must go through life worrying about whether someone will leap forward to provide help if the need ever arises. Wouldn't you feel more secure when around larger groups? After all, there's "safety in numbers." Logically, as group size increases, the probability of having a "good Samaritan" on the scene increases. Or does it?

We've seen before that human behavior isn't necessarily logical. When it comes to helping behavior, many studies have uncovered an apparent paradox called the *bystander effect:* **People are less likely to provide needed help when they are in groups than when they are alone.** Evidence that your probability of getting help *declines* as group size increases was first described by John Darley and Bibb Latané (1968), who were conducting research on the determinants of helping behavior. In the Darley and Latané study, students in individual cubicles connected by an intercom participated in discussion groups of three sizes. (The separate cubicles allowed the researchers to examine each individual's behavior in a group context, a technique that minimizes confounded variables in individual-group comparisons.) Early in the discussion, a student who was an experimental accomplice hesitantly mentioned that he was prone to seizures. Later in the discussion, the same accomplice feigned a severe seizure and cried out for help. Although a majority of subjects sought assistance for the student, the tendency to seek help *declined* with increasing group size.

Similar trends have been seen in many other experiments, in which over 6000 subjects have had opportunities to respond to apparent emergencies, including fires, asthma attacks, faintings, crashes, and flat tires, as well as less pressing needs to answer a door or to pick up objects dropped by a stranger (Latané & Nida, 1981). Many of the experiments have been highly realistic studies conducted in subways, stores, and shopping malls, and many have compared individuals against groups in face-to-face

interaction. Pooling the results of this research, Latané and Nida (1981) estimated that subjects who were alone provided help 75% of the time, whereas subjects in the presence of others provided help only 53% of the time. They concluded that the only significant limiting condition on the bystander effect is that it is less likely to occur when the need for help is unambiguous. For example, the bystander effect is less likely when someone is in obvious physical danger (Fischer et al., 2006).

What accounts for the bystander effect? A number of factors may be at work. Bystander effects are most likely in ambiguous situations because people look around to see whether others think there's an emergency. If everyone hesitates, their inaction suggests that there's no real need for help. The *diffusion of responsibility* that occurs in a group is also important. If you're by yourself when you encounter someone in need of help, the responsibility to provide help rests squarely on your shoulders. However, if other people are present, the responsibility is divided among you, and you may all say to yourselves, "Someone else will help." A reduced sense of responsibility may contribute to other aspects of behavior in groups, as we'll see in the next section.

Group Productivity and Social Loafing

Have you ever driven through a road construction project—at a snail's pace, of course—and become irritated because so many workers seem to be just standing around? Maybe the irony of the posted sign "Your tax dollars at work" made you imagine that they were all dawdling. And then again, perhaps not. Individuals' productivity often *does* decline in larger groups (Karau & Williams, 1993). This fact is unfortunate, as many important tasks can only be accomplished in groups. Group productivity is crucial to committees, sports teams, firefighting crews, sororities, study groups, symphonies, and work teams of all kinds, from the morning crew in a little diner to the board of directors of a Fortune 500 company.

Two factors appear to contribute to reduced individual productivity in larger groups. One factor is *reduced efficiency* resulting from the *loss of coordination* among workers' efforts. As you put more people on a yearbook staff, for instance, you'll probably create more and more duplication of effort and increase how often group members end up working at cross purposes.

The second factor contributing to low productivity in groups involves *effort* rather than efficiency. *Social loafing* **is a reduction in effort by individuals when they work in groups as compared to when they work by themselves.** To investigate social loafing, Latané and his colleagues (1979) measured the sound output produced by subjects who were asked to cheer or clap as loud as they could. So they couldn't see or hear other group members, subjects were told that the study concerned the importance of sensory feedback and were asked to don blindfolds and put on headphones through which loud noise was played. This maneuver permitted a simple deception: Subjects were *led to believe* that they were working alone or in a group of two or six, when in fact *individual* output was actually measured.

When participants *thought* that they were working in larger groups, their individual output declined. Since lack of coordination could not affect individual output, the subjects' decreased sound production had to be due to reduced effort. Latané and his colleagues also had the same subjects clap and shout in genuine groups of two and six and found an additional decrease in production that was attributed to loss of coordination. **Figure 16.17** on the next page shows how social loafing and loss of coordination combined to reduce productivity as group size increased.

The social-loafing effect has been replicated in numerous studies in which subjects have worked on a variety of tasks, including cheering, pumping air, swimming in a relay race, solving mazes, evaluating editorials, and brainstorming for new ideas (Karau & Williams, 1995; Levine & Moreland, 1998). Social loafing and the bystander effect appear to share a common cause: diffusion of responsibility in groups (Comer, 1995; Latané, 1981). As group size increases, the responsibility for getting a job done is divided among more people, and many group members ease up because their individual contribution is less recognizable. Thus, social loafing occurs in situations where individuals can "hide in the crowd" (Karau & Williams, 1993).

Social loafing is *not* inevitable. For example, people with high achievement motivation are less likely to exhibit social loafing than others (Hart et al., 2004). People who score high on the personality traits of agreeableness and conscientiousness are also less prone to social loafing (Klehe & Anderson, 2007). Social loafing is less likely when individuals' personal contributions to productivity are readily identifiable (Hoigaard & Ingvaldsen, 2006) and when group norms encour-
Figure 16.17

The effect of loss of coordination and social loafing on group productivity. The amount of sound produced per person declined noticeably when people worked in actual groups of two or six (orange line). This decrease in productivity reflects both loss of coordination and social loafing. Sound per person also declined when subjects merely thought they were working in groups of two or six (purple line). This smaller decrease in productivity is due to social loafing.

Adapted by permission of the author.

age productivity and personal involvement (Hoigaard, Safvenbom, & Tonnessen, 2006). And social loafing is reduced when people work in smaller and more cohesive groups (Liden et al., 2004). Cultural factors may also influence the likelihood of social loafing. Studies with subjects from Japan, China, and Taiwan suggest that social loafing may be less prevalent in collectivistic cultures, which place a high priority on meeting group goals and contributing to one's ingroups (Karau & Williams, 1995; Smith, 2001).

Decision Making in Groups

Productivity is not the only issue that commonly concerns groups. When people join together in groups, they often have to make decisions about what the group will do and how it will use its resources. Whether it's your study group deciding what type of pizza to order, a jury deciding on a verdict, or Congress deciding on whether to pass a bill, groups make decisions.

Evaluating decision making is often more complicated than evaluating productivity. In many cases, the "right" decision may not be readily apparent. Who can say whether your study group ordered the right pizza or whether Congress passed the right bills? Nonetheless, social psychologists have discovered some interesting tendencies in group decision making.

Group Polarization

Who leans toward more cautious decisions: individuals or groups? Common sense suggests that groups will work out compromises that cancel out members' extreme views. Hence, the collective wisdom of the group should yield relatively conservative choices. Is common sense correct? To investigate this question, Stoner (1961) asked individual subjects to give their recommendations on tough decisions and then asked the same subjects to engage in group discussion to arrive at joint recommendations. When Stoner compared individuals' average recommendation against their group decision generated through

concept check 16.4

Scrutinizing Common Sense

Check your understanding of the implications of research in social psychology by indicating whether the common-sense assertions listed below have been supported by empirical findings. Do the trends in research summarized in this chapter indicate that the following statements are true or false? The answers are in Appendix A.

_____ **1.** Generally, in forming their impressions of others, people don't judge a book by its cover.

_____ **2.** When it comes to attraction, birds of a feather flock together.

_____ **3.** In the realm of love, opposites attract.

_____ **4.** If you're the target of persuasion, to be forewarned is to be forearmed.

_____ **5.** When you need help, there's safety in numbers.

discussion, he found that groups arrived at *riskier* decisions than individuals did. Stoner's finding was replicated in other studies (Pruitt, 1971), and the phenomenon acquired the name *risky shift.*

However, investigators eventually determined that groups can shift either way, toward risk or caution, depending on which way the group is leaning to begin with (Friedkin, 1999). A shift toward a more extreme position, an effect called *polarization,* is often the result of group discussion (Tindale, Kameda, & Hinsz, 2003). Thus, **group polarization occurs when group discussion strengthens a group's dominant point of view and produces a shift toward a more extreme decision in that direction** (see **Figure 16.18**). Group polarization does *not* involve widening the gap between factions in a group, as its name might suggest. In fact, group polarization can contribute to consensus in a group, as we'll see in our discussion of groupthink.

Groupthink

In contrast to group polarization, which is a normal process in group dynamics, groupthink is more like a "disease" that can infect decision making in groups.

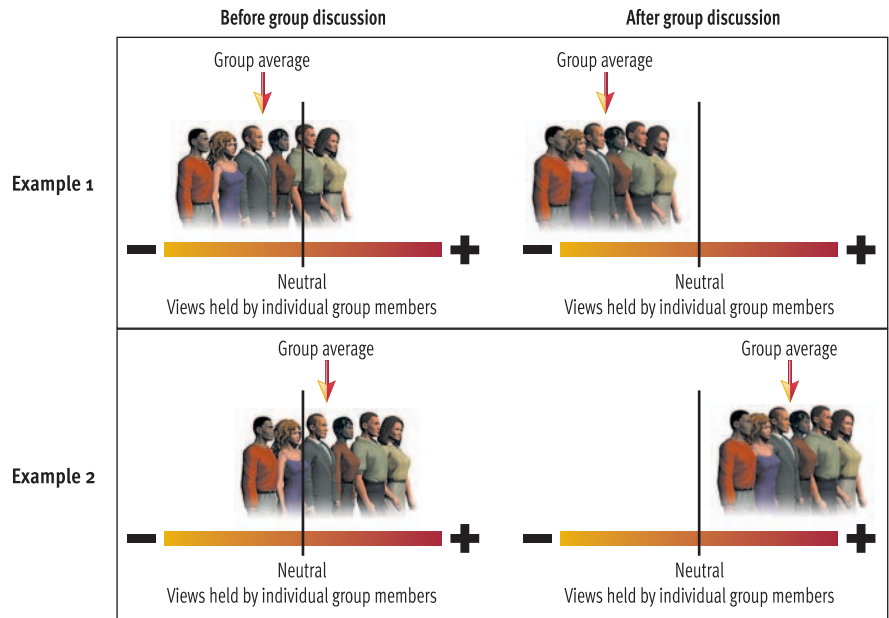

Figure 16.18

Group polarization. Two examples of group polarization are diagrammed here. The positions of the people on the horizontal scales reflect their positive or negative attitudes regarding an idea before and after group discussion. In the first example (top) a group starts out mildly opposed to an idea, but after discussion sentiment against the idea is stronger. In the second example (bottom), a group starts out with a favorable disposition toward an idea, and this disposition is strengthened by group discussion.

Many types of groups have to arrive at collective decisions. The social dynamics of group decisions are complicated, and a variety of factors can undermine effective decision making.

© Joseph Pobereskin/Stone/Getty Images

Groupthink **occurs when members of a cohesive group emphasize concurrence at the expense of critical thinking in arriving at a decision.** As you might imagine, groupthink doesn't produce very effective decision making. Indeed, groupthink can lead to major blunders that may look incomprehensible after the fact. Irving Janis (1972) first described groupthink in his effort to explain how President John F. Kennedy and his advisers could have miscalculated so badly in deciding to invade Cuba at the Bay of Pigs in 1961. The attempted invasion failed miserably and, in retrospect, seemed remarkably ill-conceived.

Applying his many years of research and theory on group dynamics to the Bay of Pigs fiasco, Janis developed a model of groupthink. When groups get caught up in groupthink, members suspend their critical judgment and the group starts censoring dissent as the pressure to conform increases. Soon, everyone begins to think alike. Moreover, "mind guards" try to shield the group from information that contradicts the group's view.

If the group's view is challenged from outside, victims of groupthink tend to think in simplistic "us versus them" terms. Members begin to overestimate the ingroup's unanimity, and they begin to view the outgroup as the enemy. Groupthink also promotes incomplete gathering of information. Like individuals, groups often display a confirmation bias, as they tend to seek and focus on information that supports their initial views (Schulz-Hardt et al., 2000).

What causes groupthink? According to Janis, a key precondition is high group cohesiveness. *Group cohesiveness* **refers to the strength of the liking relationships linking group members to each other and to the group itself.** Members of cohesive groups are close-knit, are committed, have "team spirit," and are loyal to the group. Cohesiveness itself isn't bad. It can facilitate group productivity (Mullen & Copper, 1994) and help groups achieve great things. But Janis maintains that the danger of groupthink is greater when groups are highly cohesive. Groupthink is also more likely when a group

works in relative isolation, when the group's power structure is dominated by a strong, directive leader, and when the group is under stress to make a major decision. Under these conditions, group discussions can easily lead to group polarization, strengthening the group's dominant view.

A relatively small number of experiments have been conducted to test Janis's theory, because the antecedent conditions thought to foster groupthink—such as high decision stress, strong group cohesiveness, and dominating leadership—are difficult to create effectively in laboratory settings (Aldag & Fuller, 1993). The studies that have been conducted have yielded mixed results in that high cohesiveness and strong leadership do not *necessarily* produce groupthink (Baron, 2005; Kerr & Tindale, 2004). Thus, the evidence on groupthink consists mostly of retrospective case studies of major decision-making fiascos (Eaton, 2001). In light of this situation, Janis's model of groupthink should probably be characterized as an innovative, sophisticated, intuitively appealing theory that needs to be subjected to much more empirical study.

Favorable Effects in Groups

After reading about group polarization and groupthink you may be thinking that decision making in groups is fundamentally flawed, but groups have their advantages as well as their disadvantages. For example, Forsyth (2006) notes that investment groups are superior to individuals in picking stocks, that groups exhibit greater accuracy than individuals on person perception tasks, and that teams of physicians generate better diagnoses than individual physicians. Research also shows that teams of students outperform individual students on academic tests (Zimbardo, Butler, & Wolfe, 2003). And studies have demonstrated that groups are better than individuals at solving complicated logic problems (Laughlin et al., 2003, 2006). So, although group decision making can go awry, groups are nonetheless superior to individuals on many types of tasks.

Reflecting on the Chapter's Themes

Our discussion of social psychology has provided a final embellishment on three of our seven unifying themes. One of these is the value of psychology's commitment to empiricism—that is, its reliance on systematic observation through research to arrive at conclusions. The second theme that stands out is the importance of cultural factors in shaping behavior, and the third is the extent to which people's experience of the world is highly subjective. Let's consider the virtues of empiricism first.

It's easy to question the need to do scientific research on social behavior, because studies in social psychology often seem to verify common sense. While most people wouldn't presume to devise their own theory of color vision, question the significance of REM sleep, or quibble about the principal causes of schizophrenia, everyone has beliefs about the nature of love, how to persuade others, and people's willingness to help in times of need. Thus, when studies demonstrate that credibility enhances persuasion, or that good looks facilitate attraction, it's tempting to conclude that social psychologists go to great lengths to document the obvious, and some critics say, "Why bother?"

You saw why in this chapter. Research in social psychology has repeatedly shown that the predictions of logic and common sense are often wrong. Consider just a few examples. Even psychiatric experts failed to predict the remarkable obedience to authority uncovered in Milgram's research. The bystander effect in helping behavior violates cold-blooded mathematical logic. Dissonance research has shown that after a severe initiation, the bigger the letdown, the more favorable people's feelings are. These principles defy common sense. Thus, research on social behavior provides dramatic illustrations of why psychologists put their faith in empiricism.

Our coverage of social psychology also demonstrated once again that, cross-culturally, behavior is characterized by both variance and invariance. Thus, we saw substantial cultural differences in patterns of attribution, the role of romantic love in marriage, attitudes about conformity, the tendency to obey authority figures, and the likelihood of social loafing. Although basic social phenomena such as stereotyping, attraction, obedience, and conformity probably occur all over the world, cross-cultural studies of social behavior show that research findings based on American samples may not generalize precisely to other cultures.

Research in social psychology is also uniquely suited for making the point that people's view of the world is highly personal and subjective. In this chapter we saw how physical appearance can color perception of a person's ability or personality, how stereotypes can lead people to see what they expect to see in their interactions with others, how pressure to conform can make people begin to doubt their senses, and how groupthink can lead group members down a perilous path of shared illusions.

The subjectivity of social perception will surface once again in our Applications for the chapter. The Personal Application focuses on prejudice, a practical problem that social psychologists have shown great interest in, whereas the Critical Thinking Application examines aspects of social influence.

REVIEW of Key Learning Goals

16.25 Our study of social psychology highlighted three of the text's unifying themes: the value of empiricism, the cultural limits of research based on American samples, and the subjectivity of perception.

Understanding Prejudice

Answer the following "true" or "false."

____ **1** Prejudice and discrimination amount to the same thing.

____ **2** Stereotypes are always negative or unflattering.

____ **3** Ethnic and racial groups are the only widespread targets of prejudice in modern society.

____ **4** People see members of their own ingroup as being more alike than the members of outgroups.

James Byrd Jr., a 49-year-old black man, was walking home from a family gathering in the summer of 1998 when he was offered a ride by three white men, one of whom he knew. Shortly thereafter, pieces of Byrd's savagely beaten body were found strewn along a rural road in Texas. Apparently, he had been beaten, then shackled by his ankles to the back of the truck and dragged to death over 2 miles of road. Police say that Byrd was targeted simply because he was black. Thankfully, such tragic events are relatively rare in the United States. Nonetheless, they remind us that prejudice and discrimination still exist.

Prejudice is a major social problem. It harms victims' self-concepts, suppresses their potential, creates enormous stress in their lives, and promotes tension and strife between groups (Dion, 2003). The first step toward reducing prejudice is to understand its roots. Hence, in this Application, we'll try to achieve a better understanding of why prejudice is so common. Along the way, you'll learn the answers to the true-false questions on the previous page.

Prejudice and discrimination are closely related concepts, and the terms have become nearly interchangeable in popular use. Social scientists, however, prefer to define their terms precisely, so let's clarify the concepts. **Prejudice is a negative attitude held toward members of a group.** Like many other attitudes, prejudice can include three components (see **Figure 16.19**): beliefs ("Indians are mostly alcoholics"), emotions ("I despise Jews"), and behavioral dispositions ("I wouldn't hire a Mexican"). Racial prejudice receives the lion's share of publicity, but prejudice is *not* limited to ethnic groups. Women, homosexuals, the aged, the disabled, and the mentally ill are also targets of widespread prejudice. Thus, many people hold prejudicial attitudes toward one group or another, and many have been victims of prejudice.

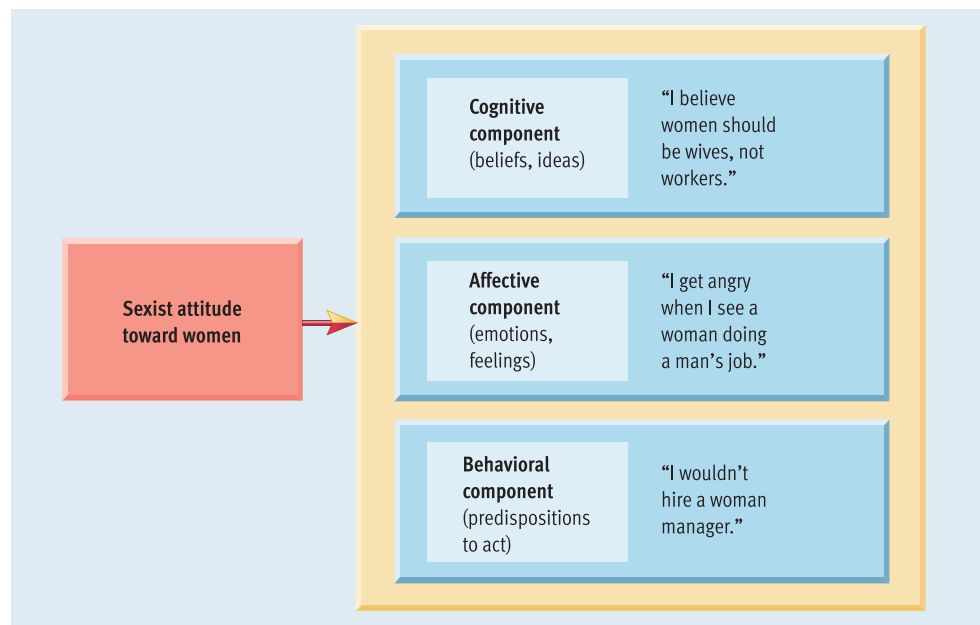
Prejudice may lead to **discrimination, which involves behaving differently, usually unfairly, toward the members of a group.** Prejudice and discrimination tend to go hand in hand, but as LaPiere's (1934) pioneering study of discrimination in restaurant seating showed (see p. 682), attitudes and behavior do not necessarily correspond


Figure 16.19

The three potential components of prejudice as an attitude. Attitudes can consist of up to three components. The tricomponent model of attitudes, applied to prejudice against women, would view sexism as negative beliefs about women (cognitive component) that lead to a feeling of dislike (affective component), which in turn leads to a readiness to discriminate against women (behavioral component).

(Hogg & Abrams, 2003; see **Figure 16.20**). In our discussion, we'll concentrate primarily on the attitude of prejudice. Let's begin by looking at processes in person perception that promote prejudice.

Stereotyping and Subjectivity in Person Perception 12d

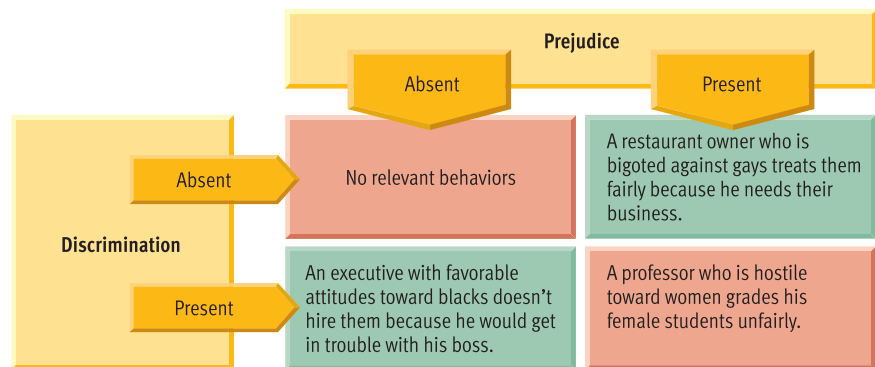
Perhaps no factor plays a larger role in prejudice than *stereotypes*. That's not to say that stereotypes are inevitably negative. For instance, it's hardly insulting to assert that Americans are ambitious or that the Japanese are industrious. Unfortunately, many people do subscribe to derogatory stereotypes of various ethnic groups. Although studies suggest that negative racial stereotypes have diminished over the last 50 years, they're not a thing of the past (Madon et al., 2001; Mellor, 2003). Not surprisingly, white Americans tend to think more progress has occurred toward racial equality


Figure 16.20

Relationship between prejudice and discrimination. As these examples show, prejudice can exist without discrimination and discrimination without prejudice. In the green cells, there is a disparity between attitude and behavior.

than black Americans do (Eibach & Keegan, 2006). According to a variety of investigators, modern racism has merely become more subtle (Devine, Plant, & Blair, 2001; Dovidio & Gaertner, 2000, 2008). Many people carefully avoid overt expressions of prejudicial attitudes but covertly continue to harbor negative views of racial minorities. These people endorse racial equality as an abstract principle but often oppose concrete programs intended to promote equality, on the grounds that discrimination is no longer a problem (Wright & Taylor, 2003). Studies suggest that modern sexism has become subtle in much the same way as racism (Swim & Campbell, 2001).

Research indicates that prejudicial stereotypes are so pervasive and insidious they often operate automatically (Amodio et al., 2004; Fiske, 2000), even in people who truly renounce prejudice. Thus, a man who rejects prejudice against homosexuals may still feel uncomfortable sitting next to a gay male on a bus, even though he regards his reaction as inappropriate.

Unfortunately, stereotypes are highly resistant to change. When people encounter members of a group that they view with prejudice who deviate from the stereotype of that group, they often find ways to discount this evidence. For example, people who are high in prejudice tend to attribute minorities' stereotype-consistent behavior to internal factors (the person), whereas they attribute stereotype-inconsistent behavior to external factors (the situation). This pattern of thinking allows people to preserve their stereotypes (Sherman et al., 2005).

Stereotypes also persist because the *subjectivity* of person perception makes it likely that people will see what they expect to see when they actually come into contact with groups that they view with prejudice (Dunning & Sherman, 1997). For example, Dun-

 can (1976) had white subjects watch and evaluate interaction on a TV monitor that was supposedly live (it was actually a videotape) and varied the race of a person who gets into an argument and gives another person a slight shove. The shove was coded as "violent behavior" by 73% of the subjects when the actor was black but by only 13% of the subjects when the actor was white. As we've noted before, people's perceptions are highly subjective. Because of stereotypes, even "violence" may lie in the eye of the beholder.

Memory biases are also tilted in favor of confirming people's prejudices (Ybarra, Stephan, & Schaberg, 2000). For example, if a man believes that "women are not cut out for leadership roles," he may dwell with delight on his female supervisor's mistakes and quickly forget about her achievements. Thus, the *illusory correlation effect* can contribute to the maintenance of prejudicial stereotypes (Berndsen et al., 2002).

Members of many types of groups are victims of prejudice. Besides racial minorities, others that have been stereotyped and discriminated against include gays and lesbians, women, the homeless, and those who are overweight.

Biases in Attribution

Attribution processes can also help perpetuate stereotypes and prejudice (Maass, 1999). Research taking its cue from Weiner's (1980) model of attribution has shown that people often make *biased attributions for success and failure.* For example, men and women don't get equal credit for their successes (Swim & Sanna, 1996). Observers often discount a woman's success by attributing it to good luck, sheer effort, or the ease of the task (except on traditional feminine tasks). In comparison, a man's success is more likely to be attributed to his outstanding ability (see **Figure 16.21**). For example, one recent study found that when a man and woman collaborate on a stereotypically "male" task, both male and female observers downplay the woman's contribution (Heilman & Haynes, 2005). These biased patterns of attribution help sustain the stereotype that men are more competent than women.

Recall that the *fundamental attribution error* is a bias toward explaining events by pointing to the actor's personal characteristics as causes (internal attributions). Research suggests that people are particularly likely to make this error when evaluating targets of prejudice (Hewstone, 1990). Thus, when people take note of ethnic neighborhoods dominated by crime and poverty, the personal qualities of the residents are blamed for these problems, whereas other explanations emphasizing situational factors (job discrimination, poor police service, and so on) are downplayed or ignored. The old saying "They should be able to pull themselves up by their bootstraps" is a blanket dismissal of how situational factors may make it especially difficult for minorities to achieve upward mobility.

Defensive attribution, which involves unjustly blaming victims of misfortune for their adversity, can also contribute to prejudice. A prominent example in recent years has been the assertion by some people that homosexuals brought the AIDS crisis on themselves and so deserve their fate (Anderson, 1992). By blaming AIDS on gays' alleged character flaws, heterosexuals may be unknowingly seeking to reassure themselves that they're immune to a similar fate.

Forming and Preserving Prejudicial Attitudes

If prejudice is an attitude, where does it come from? Many prejudices appear to be handed down as a legacy from parents (Ponterotto & Pedersen, 1993). Prejudicial attitudes can be found in children as young as ages 4 or 5 (Aboud & Amato, 2001). Research suggests that parents' racial attitudes often influence their children's racial attitudes (Sinclair, Dunn, & Lowery, 2004). This transmission of prejudice across generations presumably depends to some extent on *observational learning.* For example, if a young boy hears his father ridicule homosexuals, his exposure to his father's attitude is likely to affect his attitude about gays. If the young boy then goes to school and makes disparaging remarks about gays that are reinforced by approval from peers, his prejudice will be strengthened through *operant conditioning.* Of course, prejudicial attitudes are not acquired only through direct experience. Stereotypic portrayals of various groups in the media can also foster prejudicial attitudes (Williams & Giles, 1998; Mastro, Behm-Morawitz, Kopacz, 2008).

Competition Between Groups

One of the oldest and simplest explanations for prejudice is that competition between groups can fuel animosity. If two groups compete for scarce resources, such as good jobs and affordable housing, one group's gain is the other's loss. *Realistic group conflict theory* asserts that intergroup hostility and prejudice are a natural outgrowth of fierce competition between groups.

A classic study at Robbers' Cave State Park in Oklahoma provided support for this theory many years ago (Sherif et al., 1961). The subjects were 11-year-old white boys attending a three-week summer camp at the park, who did not know that the camp counselors were actually researchers (their parents knew). The boys were randomly assigned to one of two groups. During the first week, the boys got to know the other members of their own group through typical camp activities and developed a group identity, choosing to call themselves the Rattlers and the Eagles. In the second week, the Rattlers and Eagles were put into a series of competitive situations, such as a football game, a treasure hunt, and a tug of war, with trophies and other prizes at stake. As predicted by realistic group conflict theory, hostile feelings quickly erupted between the two groups, as food fights broke out in the mess hall, cabins were ransacked, and group flags were burned.

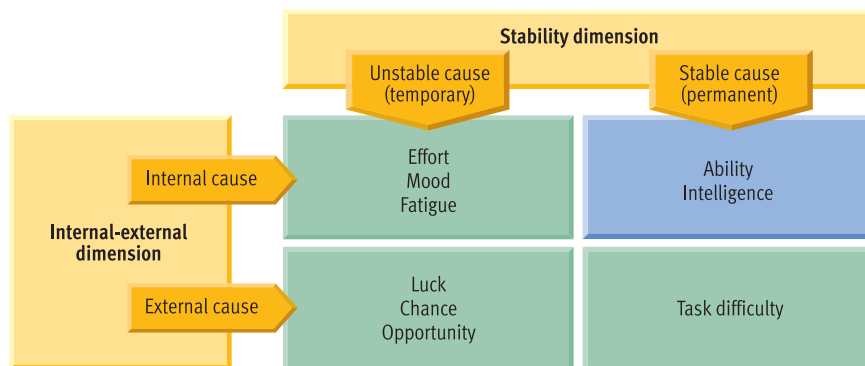
If competition between innocent groups of children pursuing trivial prizes can foster hostility, you can imagine what is likely to happen when adults from very different


Figure 16.21

Bias in the attributions used to explain success and failure by men and women. Attributions about the two sexes often differ. For example, men's successes tend to be attributed to their ability and intelligence (blue cell), whereas women's successes tend to be attributed to hard work, good luck, or low task difficulty (green cells). These attributional biases help to perpetuate the belief that men are more competent than women.

backgrounds battle for genuinely important resources. Research has repeatedly shown that conflict over scarce resources can fuel prejudice and discrimination (Bourhis & Gagnon, 2001). Even the mere *perception* of competition can breed prejudice (Zarate et al., 2004).

Dividing the World into Ingroups and Outgroups

12d

As noted in the main body of the chapter, when people join together in groups, they sometimes divide the social world into "us versus them," or *ingroups versus outgroups.* As you might anticipate, people tend to evaluate outgroup members less favorably than ingroup members (Krueger, 1996; Reynolds, Turner, & Haslam, 2000). People also tend to think simplistically about outgroups. They tend to see diversity among the members of their own group but to overestimate the homogeneity of the outgroup (Boldry, Gaertner, & Quinn, 2007). At a simple, concrete level, the essence of this process is captured by the statement "They all look alike." The illusion of homogeneity in the outgroup makes it easier to sustain stereotypic beliefs about its members (Rothbart, 2001). This point disposes of our last unanswered question from the list that opened the Application. Just in case you missed one of the answers, the statements were all false.

Threats to Social Identity

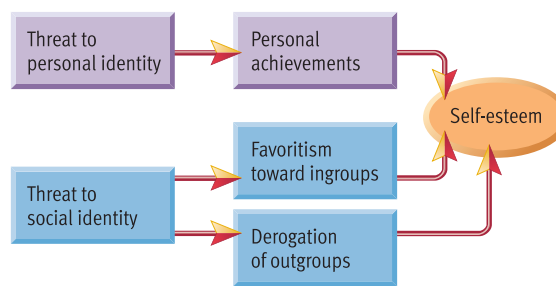
According to the *social identity perspective,* self-esteem depends on both one's *personal* identity and one's *social* identity (Tajfel & Turner, 1979; Turner et al., 1987). *Social identity* refers to the pride individuals derive from their membership in various groups, such as ethnic groups, religious denominations, occupational groups, neighborhoods,


Figure 16.22

Threats to social identity and prejudice. According to Tajfel (1982) and Turner (1987), individuals have both a personal identity (based on a unique sense of self) and a social identity (based on group memberships). When social identity is threatened, people are motivated to restore self-esteem by either showing favoritism to ingroup members or derogating members of outgroups. These tactics contribute to prejudice and discrimination. (Adapted from Brehm & Kassin, 1993)

country clubs, and so forth. The theory further proposes that self-esteem can be undermined by either threats to personal identity (you didn't get called for that job interview) or social identity (your football team loses a big game). Threats to both personal and social identity may motivate efforts to restore self-esteem, but threats to social identity are more likely to provoke responses that foster prejudice and discrimination.

When social identity is threatened, individuals may react in two key ways to bolster it (see **Figure 16.22**). One common response is to show *ingroup favoritism*—for example, tapping an ingroup member for a job opening or rating the performance of an ingroup member higher than that of an outgroup member (Capozza & Brown, 2000). A second common reaction is to engage in *outgroup derogation*—in other words, to "trash" outgroups that are perceived as threatening. Outgroup derogation is more likely when people identify especially strongly with the threatened ingroup (Levin et al, 2003; Schmitt & Maes, 2002). When people derogate an outgroup, they tend to feel superior as a result, and this feeling helps affirm their self-worth (Fein & Spencer, 1997). These unfortunate reactions are *not* inevitable, but threats to social identity represent yet another dynamic process that can foster prejudice (Turner & Reynolds, 2001).

Our discussion has shown that a plethora of processes conspire to create and maintain personal prejudices against a di-

verse array of outgroups. Most of the factors at work reflect normal, routine processes in social behavior. Thus, it is understandable that most people—whether privileged or underprivileged, minority members or majority members—probably harbor some prejudicial attitudes. Our analysis of the causes of prejudice may have permitted you to identify prejudices of your own or their sources. Perhaps it's wishful thinking on my part, but an enhanced awareness of your personal prejudices may help you become a little more tolerant of the endless diversity seen in human behavior. If so, that alone would mean that my efforts in writing this book have been amply rewarded.

REVIEW of Key Learning Goals

16.26 Prejudice is supported by selectivity and memory biases in person perception and stereotyping. Stereotypes are highly resistant to change. Attributional biases, such as the tendency to assume that others' behavior reflects their dispositions, can contribute to prejudice. The tendency to attribute others' failures to personal factors and the tendency to derogate victims can also foster prejudice.

16.27 Negative attitudes about groups are often acquired through observational learning and strengthened through operant conditioning. Realistic group conflict theory posits that competition between groups for scarce resources fosters prejudice.

16.28 People tend to be biased in favor of their ingroups. The propensity to see outgroups as homogenous serves to strengthen prejudice. Threats to social identity can lead to ingroup favoritism and outgroup derogation.

Whom Can You Trust? Analyzing Credibility and Influence Tactics

Key Learning Goals

16.29 Identify useful criteria for evaluating credibility, and recognize standard social influence strategies.

You can run, but you cannot hide. This statement aptly sums up the situation that exists when it comes to persuasion and social influence. There is no way to successfully evade the constant, pervasive, omnipresent efforts of others to shape your attitudes and behavior. In this Application we will address two topics that can enhance your resistance to manipulation. First, we will outline some ideas that can be useful in evaluating the credibility of a persuasive source. Second, we will describe some widely used social influence strategies that it pays to know about.

Evaluating Credibility

The salesperson at your local health food store swears that a specific herb combination improves memory and helps people stay healthy. A popular singer touts a psychic hotline, where the operators can "really help" with the important questions in life. Speakers at a "historical society" meeting claim that the Holocaust never happened. These are just a few real-life examples of the pervasive attempts to persuade the public to believe something. In these examples, the "something" people are expected to believe runs counter to the conventional or scientific view, but who is to say who is right? After all, people are entitled to their own opinions, aren't they?

Yes, people *are* entitled to their own opinions, but that does not mean that all opinions are equally valid. Some opinions are just plain wrong, and others are highly dubious. Every person is not equally believable. In deciding what to believe, it is important to carefully examine the evidence presented and the logic of the argument that supports the conclusion (see the Critical Thinking Application for Chapter 10). You also need to decide *whom* to believe,

a task that requires assessing the *credibility* of the source of the information. Following are a few questions that can provide guidance in this decision-making process.

Does the source have a vested interest in the issue at hand? If the source is likely to benefit in some way from convincing you of something, you need to take a skeptical attitude. In the examples provided here, it is easy to see how the sales clerk and popular singer will benefit if you buy the products they are selling, but what about the so-called historical society? How would members benefit by convincing large numbers of people that the Holocaust never happened? Like the sales clerk and singer, they are also selling something, in this case a particular view of history that they hope will influence future events in certain ways. Someone does *not* have to have a financial gain at stake to have a vested interest in an issue. Of course, the fact that these sources have a vested interest does not necessarily mean that the information they are providing is false or that their arguments are invalid. But a source's credibility does need to be evaluated with extra caution when the person or group has something to gain.

What are the source's credentials? Does the person have any special training, an advanced degree, or any other basis for claiming special knowledge about the topic? The usual training for a sales clerk or singer does not include how to assess research results in medical journals or claims of psychic powers. The Holocaust deniers are more difficult to evaluate. Some of them have studied history and written books on the topic, but the books are mostly self-published and few of these "experts" hold positions at reputable universities where scholars are subject to peer evaluation. That's *not* to say that legitimate credentials ensure a source's credibility. A number of popular diets that are widely regarded by nutritional experts as worthless, if not hazardous, have been created and marketed by genuine physicians (Drewnowski, 1995; Dwyer, 1995). Of

course, these physicians have a *vested interest* in the diets, as they have made millions of dollars from them.

Is the information grossly inconsistent with the conventional view on the issue? Just being different from the mainstream view certainly does *not* make a conclusion wrong. But claims that vary radically from most other information on a subject should raise a red flag that leads to careful scrutiny. Bear in mind that charlatans and hucksters are often successful because they typically try to persuade people to believe things that they want to believe. Wouldn't it be great if we could effortlessly enhance our memory, foretell the future, eat all we want and still lose weight, and earn hundreds of dollars per hour working at home? And wouldn't it be nice if the Holocaust never happened? It pays to be wary of wishful thinking.

What was the method of analysis used in reaching the conclusion? The purveyors of miracle cures and psychic advice inevitably rely on anecdotal evidence. But you have already learned about the perils and unreliability of anecdotal evidence (see Chapter 2). One method frequently used by charlatans is to undermine the credibility of conventional information by focusing on trivial inconsistencies. This is one of the many strategies used by the people who argue that the Holocaust never occurred. They question the credibility of thousands of historical documents, photographs, and artifacts, and the testimony of countless people, by highlighting small inconsistencies among historical records relating to trivial matters, such as the number of people transported to a concentration camp in a specific week, or the number of bodies that could be disposed of in a single day (Shermer, 1997). Some inconsistencies are exactly what one should expect based on piecing together multiple accounts from sources working with different portions of incomplete information. But the strategy of focusing on trivial inconsistencies is a standard method for raising doubts about cred-

ible information. For example, this strategy was used brilliantly by the defense attorneys in the O. J. Simpson murder trial.

Recognizing Social Influence Strategies

It pays to understand social influence strategies because advertisers, salespeople, and fundraisers—not to mention your friends and neighbors—frequently rely on them to manipulate your behavior. Let's look at four basic strategies: the foot-in-the-door technique, misuse of the reciprocity norm, the lowball technique, and feigned scarcity.

Door-to-door salespeople have long recognized the importance of gaining a *little* cooperation from sales targets (getting a "foot in the door") before hitting them with the real sales pitch. **The *foot-in-the-door technique* involves getting people to agree to a small request to increase the chances that they will agree to a larger request later.** This technique is widely used in all walks of life. For example, groups seeking donations often ask people to simply sign a petition first.

In an early study of the foot-in-the-door technique (Freedman & Fraser, 1966), the large request involved asking homemakers whether a team of six men doing consumer research could come into their home to classify *all* their household products. Only 22% of the control subjects agreed to this outlandish request. However, when the same request was made three days after a small request (to answer a few questions about soap preferences), 53% of the participants agreed to the large request. Why does the foot-in-the-door technique work? According to Burger (1999), quite a variety of processes contribute to its effectiveness, including people's tendency to try to behave

consistently (with their initial response) and their reluctance to renege on their sense of commitment to the person who made the initial request.

Most of us have been socialized to believe in the *reciprocity norm—the rule that we should pay back in kind what we receive from others.* Robert Cialdini (2007) has written extensively about how the reciprocity norm is used in social influence efforts. For example, groups seeking donations routinely send address labels, key rings, and other small gifts with their pleas. Salespeople using the reciprocity principle distribute free samples to prospective customers. When they return a few days later, most of the customers feel obligated to buy some of their products. The reciprocity rule is meant to promote fair exchanges in social interactions. However, when people manipulate the reciprocity norm, they usually give something of minimal value in the hopes of getting far more in return (Howard, 1995).

The lowball technique is even more deceptive. The name for this technique derives from a common practice in automobile sales, in which a customer is offered a terrific bargain on a car. The bargain price gets the customer to commit to buying the car. Soon after this commitment is made, however, the dealer starts revealing some hidden costs. Typically, the customer learns that options assumed to be included in the original price are actually going to cost extra, or that a promised low loan rate has "fallen through" leading to a higher car payment. Once they have committed to buying a car, most customers are unlikely to cancel the deal. Thus, **the *lowball technique* involves getting someone to commit to an attractive proposition before its hidden costs are revealed.** Car dealers aren't the only ones who use this

Advertisers often try to artificially create scarcity to make their products seem more desirable.

© Tony Freeman/PhotoEdit

technique. For instance, a friend might ask whether you want to spend a week with him at his charming backwoods cabin. After you accept this seemingly generous proposition, he may add, "Of course there's some work for us to do. We need to repair the pier, paint the exterior, and . . ." Lowballing is a surprisingly effective strategy (Cialdini & Trost, 1998; Gueguen, Pascual, & Dagot, 2002).

A number of years ago, Jack Brehm (1966) demonstrated that telling people they can't have something only makes them want it more. This phenomenon helps explain why companies often try to create the impression that their products are in scarce supply. Scarcity threatens your freedom to choose a product, thus creating an increased desire for the scarce commodity. Advertisers frequently feign scarcity to drive up the demand for products. Thus, we constantly see ads that scream "limited supply available," "for a limited time only," "while they last," and "time is running out." Like genuine scarcity, feigned scarcity *can* enhance the desirability of a commodity (Highhouse et al., 1998; Lynn, 1992).

Table 16.1 Critical Thinking Skills Discussed in This Application

Skill	Description
Judging the credibility of an information source	The critical thinker understands that credibility and bias are central to determining the quality of information and looks at factors such as vested interests, credentials, and appropriate expertise.
Recognizing social influence strategies	The critical thinker is aware of manipulative tactics such as the foot-in-the-door and lowball techniques, misuse of the reciprocity norm, and feigned scarcity.

Key Ideas

Person Perception: Forming Impressions of Others

▌ People tend to attribute desirable characteristics to those who are good looking. Perceptions of competence based on facial appearance, which can be made in an instant, are particularly important.

▌ Stereotypes are beliefs that lead people to expect that others will have certain characteristics because of their membership in a specific group. In interacting with others, stereotypes may lead people to see what they expect to see and to overestimate how often they see it.

Attribution Processes: Explaining Behavior

▌ Internal attributions ascribe behavior to personal traits, whereas external attributions locate the cause of behavior in the environment. Weiner's model proposes that attributions for success and failure be analyzed in terms of the stability of causes as well as along the internal-external dimension.

▌ Observers favor internal attributions to explain another's behavior (the fundamental attribution error), while actors favor external attributions to explain their own behavior. Cultures vary in their emphasis on individualism as opposed to collectivism, and these differences appear to influence attributional tendencies.

Close Relationships: Liking and Loving

▌ People tend to like and love others who are similar, who reciprocate expressions of affection, and who are physically attractive. In intimate relationships, romantic ideals influence the progress of relationships.

▌ Berscheid and Hatfield distinguished between passionate and companionate love. Sternberg built on their distinction by dividing companionate love into intimacy and commitment. Hazan and Shaver's theory suggests that love relationships in adulthood mimic attachment patterns in infancy. People tend to fall into three subtypes (secure, avoidant, or anxious-ambivalent) in their romantic relationships. Attachment style is related to many aspects of behavior.

▌ The characteristics that people seek in prospective mates are much the same around the world. However, cultures vary considerably in their emphasis on passionate love as a prerequisite for marriage. Although critics are concerned that Internet relationships are superficial and open to deception, Internet-initiated relationships appear to be just as intimate and stable as relationships forged offline.

▌ According to evolutionary psychologists, certain aspects of good looks influence attraction because they are indicators of reproductive fitness. Consistent with evolutionary theory, gender differences in mating preferences appear to transcend culture. People's courtship tactics may include deception. Mate poaching is common and appears to be universal across cultures.

Attitudes: Making Social Judgments

▌ Attitudes may be made up of cognitive, affective, and behavioral components. Attitudes vary in strength, accessibility, and ambivalence. Attitudes and behavior aren't as consistent as one might assume.

▌ A source of persuasion who is credible, expert, trustworthy, likable, and physically attractive tends to be relatively effective. Two-sided arguments, repetition, and fear arousal are effective elements in persuasive messages.

▌ Attitudes may be shaped through classical conditioning, operant conditioning, and observational learning. Festinger's dissonance theory asserts that inconsistent attitudes cause tension and that people alter their attitudes to reduce cognitive dissonance.

▌ Self-perception theory asserts that people may infer their attitudes from their behavior. The elaboration likelihood model holds that the central route to persuasion tends to yield longer-lasting attitude change than the peripheral route.

Conformity and Obedience: Yielding to Others

▌ Asch found that conformity becomes more likely as group size increases, up to a group size of four, and then levels off. If a small group isn't unanimous, conformity declines rapidly.

▌ In Milgram's study of obedience, subjects showed a remarkable tendency to follow orders to shock an innocent stranger. The generalizability of Milgram's findings has stood the test of time, but his work also helped to stimulate stricter ethical standards for research.

▌ The Asch and Milgram experiments have been replicated in many cultures. These replications have uncovered modest cultural variations in the propensity to conform or to obey an authority figure.

▌ The Stanford Prison Simulation demonstrated that social roles and other situational pressures can exert tremendous influence over social behavior. Like Milgram, Zimbardo showed that situational forces can lead normal people to exhibit surprisingly callous, abusive behavior.

Behavior in Groups: Joining with Others

▌ The bystander effect occurs primarily because a group creates diffusion of responsibility. Individuals' productivity often declines in larger groups because of loss of coordination and because of social loafing.

▌ Group polarization occurs when discussion leads a group to shift toward a more extreme decision in the direction the group was already leaning. In groupthink, a cohesive group suspends critical judgment in a misguided effort to promote agreement in decision making. Nonetheless, groups are superior to individuals on many types of decision-making tasks.

Reflecting on the Chapter's Themes

▌ Our study of social psychology illustrated the value of empiricism, the cultural limits of research based on American samples, and the subjectivity of perception.

PERSONAL APPLICATION Understanding Prejudice

▌ Prejudice is supported by selectivity and memory biases in person perception and stereotyping. Stereotypes are highly resistant to change. Attributional biases, such as the tendency to assume that others' behavior reflects their dispositions, can contribute to prejudice.

▌ Negative attitudes about groups are often acquired through observational learning and strengthened through operant conditioning. Realistic group conflict theory proposes that competition between groups fosters prejudice. The propensity to see outgroups as homogenous serves to strengthen prejudice. Threats to social identity can lead to ingroup favoritism and outgroup derogation.

CRITICAL THINKING APPLICATION Whom Can You Trust? Analyzing Credibility and Influence Tactics

▌ Useful criteria in judging credibility include whether a source has vested interests or appropriate credentials. One should also consider the method of analysis used in reaching conclusions and why information might not coincide with conventional wisdom.

▌ To resist manipulative efforts, it helps to be aware of social influence tactics, such as the foot-in-the-door technique, misuse of the reciprocity norm, the lowball technique, and feigned scarcity.

Bernard Weiner (pp. 668–669)
Philip Zimbardo (pp. 692–693)

1. Stereotypes:
   A. are often automatic products of normal cognitive processes.
   B. are widely held beliefs that people have certain characteristics because of their membership in a particular group.
   C. equivalent to prejudice.
   D. both a and b.

2. You believe that short men have a tendency to be insecure. The concept of illusory correlation implies that you will:
   A. overestimate how often short men are insecure.
   B. underestimate how often short men are insecure.
   C. overestimate the frequency of short men in the population.
   D. falsely assume that shortness in men causes insecurity.

3. A father suggests that his son's low marks in school are due to the child's laziness. The father has made a (an) _____ attribution.
   A. external   C. situational
   B. internal   D. high consensus

4. Bob explains his failing grade on a term paper by saying that he really didn't work very hard at it. According to Weiner's model, Bob is making an _____ attribution about his failure.
   A. internal-stable   C. external-stable
   B. internal-unstable   D. external-unstable

5. The fundamental attribution error refers to the tendency of:
   A. observers to favor external attributions in explaining the behavior of others.
   B. observers to favor internal attributions in explaining the behavior of others.
   C. actors to favor external attributions in explaining the behavior of others.
   D. actors to favor situational attributions in explaining their own behavior.

6. According to Hazan and Shaver (1987):
   A. romantic relationships in adulthood follow the same form as attachment relationships in infancy.
   B. those who had ambivalent attachments in infancy are doomed never to fall in love as adults.
   C. those who had avoidant attachments in infancy often overcompensate by becoming excessively intimate in their adult love relationships.
   D. all of the above are the case.

7. Cross-cultural similarities are most likely to be found in which of the following areas?
   A. what people look for in prospective mates
   B. the overall value of romantic love
   C. passionate love as a prerequisite for marriage
   D. the tradition of prearranged marriages

8. Cognitive dissonance theory predicts that after people engage in counterattitudinal behavior, they will:
   A. convince themselves they really didn't perform the behavior.
   B. change their attitude to make it more consistent with their behavior.
   C. change their attitude to make it less consistent with their behavior.
   D. do nothing.

9. "I always choose romance novels rather than biographies. I guess I must like romance novels better." This thought process illustrates the premise of _____ theory.
   A. cognitive dissonance   C. evolutionary
   B. learning   D. self-perception

10. The elaboration likelihood model of attitude change suggests that:
   A. the peripheral route results in more enduring attitude change.
   B. the central route results in more enduring attitude change.
   C. only the central route to persuasion can be effective.
   D. only the peripheral route to persuasion can be effective.

11. The results of Milgram's (1963) study imply that:
   A. in the real world, most people will refuse to follow orders to inflict harm on a stranger.

   B. many people will obey an authority figure even if innocent people get hurt.
   C. most people are willing to give obviously wrong answers when ordered to do so.
   D. most people stick to their own judgment, even when group members unanimously disagree.

12. According to Latané (1981), social loafing is due to:
   A. social norms that stress the importance of positive interactions among group members.
   B. duplication of effort among group members.
   C. diffusion of responsibility in groups.
   D. a bias toward making internal attributions about the behavior of others.

13. Groupthink occurs when members of a cohesive group:
   A. are initially unanimous about an issue.
   B. stress the importance of caution in group decision making.
   C. emphasize concurrence at the expense of critical thinking in arriving at a decision.
   D. shift toward a less extreme position after group discussion.

14. Discrimination:
   A. refers to a negative attitude toward members of a group.
   B. refers to unfair behavior toward the members of a group.
   C. is the same thing as prejudice.
   D. is all of the above.

15. The foot-in-the-door technique involves asking people to agree to a _____ request first to increase the likelihood that they will comply with a _____ request later.
   A. large; small   C. large; large
   B. small: large   D. large; larger

Answers to Concept Checks

Chapter 1

Concept Check 1.1

1. c. Sigmund Freud (1905, pp. 77–78), arguing that it is possible to probe into the unconscious depths of the mind.

2. a. Wilhelm Wundt (1874/1904, p. v), campaigning for a new, independent science of psychology.

3. b. William James (1890), commenting negatively on the structuralists' efforts to break consciousness into its elements and his view of consciousness as a continuously flowing stream.

Concept Check 1.2

1. b. B. F. Skinner (1971, p. 17), explaining why he believes that freedom is an illusion.

2. c. Carl Rogers (1961, p. 27), commenting on others' assertion that he had an overly optimistic (Polly-annaish) view of human potential and discussing humans' basic drive toward personal growth.

3. a. John B. Watson (1930, p. 103), dismissing the importance of genetic inheritance while arguing that traits are shaped entirely by experience.

Concept Check 1.3

a. 2. Psychology is theoretically diverse.

b. 6. Heredity and environment jointly influence behavior.

c. 4. Behavior is determined by multiple causes.

d. 7. Our experience of the world is highly subjective.

Chapter 2

Concept Check 2.1

1. IV: Film violence (present versus absent)

   DV: Heart rate and blood pressure (there are two DVs)

2. IV: Courtesy training (training versus no training)

   DV: Number of customer complaints

3. IV: Stimulus complexity (high versus low) and stimulus contrast (high versus low) (there are two IVs)

   DV: Length of time spent staring at the stimuli

4. IV: Group size (large versus small)

   DV: Conformity

Concept Check 2.2

1. d. Survey. You would distribute a survey to obtain information on subjects' social class, education, and attitudes about nuclear disarmament.

2. c. Case study. Using a case study approach, you could interview people with anxiety disorders, interview their parents, and examine their school records to look for similarities in childhood experiences. As a second choice, you might have people with anxiety disorders fill out a survey about their childhood experiences.

3. b. Naturalistic observation. To answer this question properly, you would want to observe baboons in their natural environment, without interference.

4. a. Experiment. To demonstrate a causal relationship, you would have to conduct an experiment. You would manipulate the presence or absence of food-related cues in controlled circumstances where subjects had an opportunity to eat some food, and monitor the amount eaten.

Concept Check 2.3

1. b and e. The other three conclusions all equate correlation with causation.

2. a. Negative. As age increases, more people tend to have visual problems and acuity tends to decrease.

   b. Positive. Studies show that highly educated people tend to earn higher incomes and that people with less education tend to earn lower incomes.

   c. Negative. As shyness increases, the size of one's friendship network should decrease. However, research suggests that this inverse association may be weaker than widely believed.

Concept Check 2.4

Methodological flaw	Study 1	Study 2
Sampling bias	✓	✓
Placebo effects	✓	
Confounding of variables	✓	
Distortions in self-report data		✓
Experimenter bias	✓	

Explanations for Study 1. Sensory deprivation is an unusual kind of experience that may intrigue certain potential subjects, who may be more adventurous or more willing to take risks than the population at large. Using the first 80 students who sign up for this study may not yield a sample that is representative of the population. Assigning the first 40 subjects who sign up to the experimental group may confound these extraneous variables with the treatment (students who sign up most quickly may be the most adventurous). In announcing that he will be examining the *detrimental* effects of sensory deprivation, the experimenter has created expectations in the subjects. These expectations could lead to placebo effects. The experimenter has also revealed that he has a bias about the outcome of the study. Since he supervises the treatments, he knows which subjects are in the experimental and control groups, thus aggravating potential problems with experimenter bias. For example, he might unintentionally give the control group subjects better instructions on how to do the pursuit-rotor task and thereby slant the study in favor of finding support for his hypothesis.

Explanations for Study 2. Sampling bias is a problem because the researcher has sampled only subjects from a low-income, inner-city neighborhood. A sample obtained in this way is not likely to be representative of the population at large. People are sensitive about the

issue of racial prejudice, so distortions in self-report data are also likely. Many subjects may be swayed by social desirability bias and rate themselves as less prejudiced than they really are.

Chapter 3

Concept Check 3.1

1. d. Dendrite
2. f. Myelin
3. b. Neuron
4. e. Axon
5. a. Glia
6. g. Terminal button
7. h. Synapse

Concept Check 3.2

1. d. Serotonin
2. b. and d. Serotonin and norepinephrine
3. e. Endorphins
4. c. Dopamine
5. a. Acetylcholine

Concept Check 3.3

1. Left hemisphere damage, probably to Wernicke's area
2. Deficit in dopamine synthesis in an area of the midbrain
3. Degeneration of myelin sheaths surrounding axons
4. Disturbance in dopamine activity, possibly associated with enlarged ventricles in the brain

Please note that neuropsychological assessment is not as simple as this introductory exercise may suggest. There are many possible causes of most disorders, and we discussed only a handful of leading causes for each.

Concept Check 3.4

1. Closer relatives; more distant relatives
2. Identical twins; fraternal twins
3. Biological parents; adoptive parents
4. Genetic overlap or closeness; trait similarity

Chapter 4

Concept Check 4.1

Dimension	Rods	Cones
Physical shape	Elongated	Stubby
Number in the retina	125 million	5–6.4 million
Area of the retina in which they are dominant receptor	Periphery	Center/ fovea
Critical to color vision	No	Yes
Critical to peripheral vision	Yes	No
Sensitivity to dim light	Strong	Weak
Speed of dark adaptation	Slow	Rapid

Concept Check 4.2

✓ 1. Interposition. The arches in front cut off part of the corridor behind them.

✓ 2. Height in plane. The back of the corridor is higher on the horizontal plane than the front of the corridor is.

✓ 3. Texture gradient. The more distant portions of the hallway are painted in less detail than the closer portions are.

✓ 4. Relative size. The arches in the distance are smaller than those in the foreground.

✓ 5. Light and shadow. Light shining in from the crossing corridor (it's coming from the left) contrasts with shadow elsewhere.

✓ 6. Linear perspective. The lines of the corridor converge in the distance.

Concept Check 4.3

Dimension	Vision	Hearing
1. Stimulus	Light waves	Sound waves
2. Elements of stimulus and related perceptions	Wavelength/hue Amplitude/ brightness Purity/saturation	Frequency/pitch Amplitude/ loudness Purity/timbre
3. Receptors	Rods and cones	Hair cells
4. Location of receptors	Retina	Basilar membrane
5. Main location of processing in brain	Occipital lobe, visual cortex	Temporal lobe, auditory cortex
6. Spatial aspect of perception	Depth perception	Auditory localization

Concept Check 4.4

Dimension	Taste	Smell	Touch
1. Stimulus	Soluble chemicals in saliva	Volatile chemicals in air	Mechanical, thermal, and chemical energy due to external contact
2. Receptors	Clusters of taste cells	Olfactory cilia (hairlike structures)	Many (at least 6) types
3. Location of receptors	Taste buds on tongue	Upper area of nasal passages	Skin
4. Basic elements of perception	Sweet, sour, salty, bitter	No satisfactory classification scheme	Pressure, hot, cold, pain

Chapter 5

Concept Check 5.1

Characteristic	REM sleep	NREM sleep
1. Type of EEG activity	"Wide awake" brain waves, mostly beta	Varied, lots of delta waves
2. Eye movements	Rapid, lateral	Slow or absent
3. Dreaming	Frequent, vivid	Less frequent
4. Depth (difficulty in awakening)	Varied, generally difficult to awaken	Varied, generally easier to awaken
5. Percentage of total sleep (in adults)	About 20%–25%	About 75%–80%
6. Increases or decreases (as percentage of sleep) during childhood	Percent decreases	Percent increases
7. Timing in sleep (dominates early or late)	Dominates late in cycle	Dominates early in cycle

Concept Check 5.2

1. Beta. Video games require alert information processing, which is associated with beta waves.

2. Alpha. Meditation involves relaxation, which is associated with alpha waves, and studies show increased alpha in meditators.

3. Theta. In stage 1 sleep, theta waves tend to be prevalent.

4. Delta. Sleepwalking usually occurs in deep NREM sleep, which is dominated by delta activity.

5. Beta. Nightmares are dreams, so you're probably in REM sleep, which paradoxically produces "wide awake" beta waves.

Concept Check 5.3

1. c. Stimulants.

2. d. Hallucinogens.

3. b. Sedatives.

4. f. Alcohol.

5. a. Narcotics.

6. e. Cannabis.

Chapter 6

Concept Check 6.1

1. CS: Fire in fireplace
   US: Pain from burn   CR/UR: Fear

2. CS: Brake lights in rain
   US: Car accident   CR/UR: Tensing up

3. CS: Sight of cat
   US: Cat dander   CR/UR: Wheezing

Concept Check 6.2

1. FR. Each sale is a response and every third response earns reinforcement.

2. VI. A varied amount of time elapses before the response of doing yardwork can earn reinforcement.

3. VR. Reinforcement occurs after a varied number of unreinforced casts (time is irrelevant; the more casts Martha makes, the more reinforcers she will receive).

4. CR. The designated response (reading a book) is reinforced (with a gold star) every time.

5. FI. A fixed time interval (three years) has to elapse before Skip can earn a salary increase (the reinforcer).

Concept Check 6.3

1. Punishment.

2. Positive reinforcement.

3. Punishment.

4. Negative reinforcement (for Audrey); the dog is positively reinforced for its whining.

5. Negative reinforcement.

6. Extinction. When Sharma's co-workers start to ignore her complaints, they are trying to extinguish the behavior (which had been positively reinforced when it won sympathy).

Concept Check 6.4

1. Classical conditioning. Midori's blue windbreaker is a CS eliciting excitement in her dog.

2. Operant conditioning. Playing new songs leads to negative consequences (punishment), which weaken the tendency to play new songs. Playing old songs leads to positive reinforcement, which gradually strengthens the tendency to play old songs.

3. Classical conditioning. The song was paired with the passion of new love so that it became a CS eliciting emotional, romantic feelings.

4. Both. Ralph's workplace is paired with criticism so that his workplace becomes a CS eliciting anxiety. Calling in sick is operant behavior that is strengthened through negative reinforcement (because it reduces anxiety).

Chapter 7

Concept Check 7.1

Feature	Sensory memory	Short-term memory	Long-term memory
Encoding format	Copy of input	Largely phonemic	Largely semantic
Storage capacity	Limited	Small (7±2 chunks)	No known limit
Storage duration	About 1/4 second	Up to 20 seconds	Minutes to years

Concept Check 7.2

1. Ineffective encoding due to lack of attention

2. Retrieval failure due to motivated forgetting

3. Proactive interference (previous learning of Justin Timberlake's name interferes with new learning)

4. Retroactive interference (new learning of sociology interferes with older learning of history)

Concept Check 7.3

1. a. Declarative memory

2. c. Long-term memory

3. a. Sensory memory

4. f. Episodic memory

5. e. Nondeclarative memory

6. g. Semantic memory

7. i. Prospective memory

8. b. Short-term memory

Chapter 8

Concept Check 8.1

1. 1. One-word utterance in which the word is overextended to refer to a similar object.

2. 4. Words are combined into a sentence, but the rule for past tense is overregularized.

3. 3. Telegraphic sentence.

4. 5. Words are combined into a sentence, and past tense is used correctly.

5. 2. One-word utterance without overextension.

6. 6. "Longer" sentence with metaphor.

Concept Check 8.2

1. Functional fixedness

2. Forming subgoals

3. Insight

4. Searching for analogies

5. Arrangement problem

Concept Check 8.3

1. Elimination by aspects

2. Availability heuristic

3. Shift to additive strategy

Chapter 9

Concept Check 9.1

1. Test-retest reliability

2. Criterion-related validity

3. Content validity

Concept Check 9.2

1. H. Given that the identical twins were reared apart, their greater similarity in comparison to fraternals reared together can only be due to heredity. This comparison is probably the most important piece of evidence supporting the genetic determination of IQ.

2. E. We tend to associate identical twins with evidence supporting heredity, but in this comparison genetic similarity is held constant since both sets of twins are identical. The only logical explanation for the greater similarity in identicals reared together is the effect of their being reared together (environment).

3. E. This comparison is similar to the previous one. Genetic similarity is held constant and a shared environment produces greater similarity than being reared apart.

4. B. This is nothing more than a quantification of Galton's original observation that intelligence runs in families. Since families share both genes and environment, either or both could be responsible for the observed correlation.

5. B. The similarity of adopted children to their biological parents can only be due to shared genes, and the similarity of adopted children to their foster parents can only be due to shared environment, so these correlations show the influence of both heredity and environment.

Concept Check 9.3

1. b. Gardner

2. a. Galton

3. c. Jensen

4. d. Scarr

5. e. Sternberg

Chapter 10

Concept Check 10.1

1. I. Early studies indicated that lesioning the ventromedial nucleus of the hypothalamus leads to overeating (although it is an oversimplification to characterize the VMH as the brain's "stop eating" center).

2. I. According to Mayer, hunger increases when the amount of glucose in the blood decreases.

3. I or ?. Food cues generally trigger hunger and eating, but reactions vary among individuals.

4. D. Food preferences are mostly learned, and we tend to like what we are accustomed to eating. Most people will not be eager to eat a strange-looking food.

5. I. People tend to eat more when a variety of foods are available.

6. I. Reactions vary, but stress generally tends to increase eating.

Concept Check 10.2

1. d. Fear of failure

2. c. Incentive value of success

3. b. Perceived probability of success

4. a. Need for achievement

Concept Check 10.3

2. James-Lange theory

3. Schachter's two-factor theory

4. Evolutionary theories

Chapter 11

Concept Check 11.1

	Event	Stage	Organism	Time span
1.	Uterine implantation	Germinal	Zygote	0–2 weeks
2.	Muscle and bone begin to form	Fetal	Fetus	2 months to birth
3.	Vital organs and body systems begin to form	Embryonic	Embryo	2 weeks to 2 months

Concept Check 11.2

1. b. Animism is characteristic of the preoperational period.
2. c. Mastery of hierarchical classification occurs during the concrete operational period.
3. a. Lack of object permanence is characteristic of the sensorimotor period.

Concept Check 11.3

1. c. Commitment to personal ethics is characteristic of postconventional reasoning.
2. b. Concern about approval of others is characteristic of conventional reasoning.
3. a. Emphasis on positive or negative consequences is characteristic of preconventional reasoning.

Chapter 12

Concept Check 12.1

1. Regression
2. Projection
3. Reaction formation
4. Repression
5. Rationalization

Concept Check 12.2

1. Bandura's observational learning. Sarah imitates a role model from television.
2. Maslow's need for self-actualization. Yolanda is striving to realize her fullest potential.
3. Freud's Oedipal complex. Vladimir shows preference for his opposite-sex parent and emotional distance from his same-sex parent.

Concept Check 12.3

1. Maslow (1971, p. 36), commenting on the need for self-actualization.
2. Eysenck (1977, pp. 407–408), commenting on the biological roots of personality.
3. Freud (in Malcolm, 1980), commenting on the repression of sexuality.

Chapter 13

Concept Check 13.1

1. b. A choice between two unattractive options
2. c. Weighing the positive and negative aspects of a single goal
3. a. A choice between two attractive options

Concept Check 13.2

1. a. Frustration due to delay
2. d. Pressure to perform
3. c. Change associated with leaving school and taking a new job
4. a. Frustration due to loss of job

   c. Change in life circumstances

   d. Pressure to perform (in quickly obtaining new job)

Concept Check 13.3

1. Denial of reality
2. Undoing
3. Fantasy
4. Overcompensation
5. Intellectualization

Chapter 14

Concept Check 14.1

	Deviance	Maladaptive behavior	Personal distress
1. Alan		✓	
2. Monica			✓
3. Boris	✓		
4. Natasha	✓	✓	✓

Concept Check 14.2

1. Obsessive-compulsive disorder (key symptoms: frequent rituals, ruminations about school)
2. Somatization disorder (key symptoms: history of physical complaints involving many different organ systems)
3. Conversion disorder (key symptoms: loss of function in single organ system)

Concept Check 14.3

1. Bipolar disorder, manic episode (key symptoms: extravagant plans, hyperactivity, reckless spending)
2. Paranoid schizophrenia (key symptoms: delusions of persecution and grandeur, along with deterioration of adaptive behavior)
3. Major depression (key symptoms: feelings of despair, low self-esteem, lack of energy)

Chapter 15

Concept Check 15.1

1. c   2. a   3. b

Concept Check 15.2

1. d   2. b   3. a   4. c

Concept Check 15.3

1. c   2. a   3. b   4. d   5. b

Chapter 16

Concept Check 16.1

	Unstable	*Stable*
Internal	d	b
External	a	c

Concept Check 16.2

1. c. Fundamental attribution error (assuming that arriving late reflects personal qualities)

2. a. Illusory correlation effect (overestimating how often one has seen confirmations of the assertion that young, female professors get pregnant soon after being hired)

3. b. Stereotyping (assuming that all lawyers have certain traits)

4. d. Defensive attribution (derogating the victims of misfortune to minimize the apparent likelihood of a similar mishap)

Concept Check 16.3

1. Target: Cognitive component of attitudes (beliefs about program for regulating nursing homes)

   Persuasion: Message factor (advice to use one-sided instead of two-sided arguments)

2. Target: Affective component of attitudes (feelings about candidate)

   Persuasion: Source factor (advice on appearing likable, sincere, and compassionate)

3. Target: Behavioral component of attitudes (making contributions)

   Persuasion: Receiver factor (considering audience's initial position regarding the candidate)

Concept Check 16.4

1. False   2. True   3. False   4. True   5. False

Statistical Methods

Empiricism depends on observation; precise observation depends on measurement; and measurement requires numbers. Thus, scientists routinely analyze numerical data to arrive at their conclusions. Over 3000 empirical studies are cited in this text, and all but a few of the simplest ones required a statistical analysis. *Statistics* **is the use of mathematics to organize, summarize, and interpret numerical data.** We discussed statistics briefly in Chapter 2, but in this Appendix we take a closer look.

To illustrate statistics in action, let's assume that we want to test a hypothesis that has generated quite an argument in your psychology class. The hypothesis is that college students who watch a great deal of television aren't as bright as those who watch TV infrequently. For the fun of it, your class decides to conduct a correlational study of itself, collecting survey and psychological test data. Your classmates all agree to respond to a short survey on their TV viewing habits. Because everyone at your school has had to take the SAT, the class decides to use scores on the SAT Critical Reading subtest as an index of how bright students are. All of them agree to allow the records office at the college to furnish their SAT scores to the professor, who replaces each student's name with a subject number (to protect students' right to privacy). Let's see how we could use statistics to analyze the data collected in our pilot study (a small, preliminary investigation).

Graphing Data

PSYK TREK
1c

After collecting our data, our next step is to organize the data to get a quick overview of our numerical re-

sults. Let's assume that there are 20 students in your class, and when they estimate how many hours they spend per day watching TV, the results are as follows:

3	2	0	3	1
3	4	0	5	1
2	3	4	5	2
4	5	3	4	6

One of the simpler things that we can do to organize data is to create a *frequency distribution—* **an orderly arrangement of scores indicating the frequency of each score or group of scores.** **Figure B.1(a)** shows a frequency distribution for our data on TV viewing. The column on the left lists the possible scores (estimated hours of TV viewing) in order, and the column on the right lists the number of subjects with each score. Graphs can provide an even better overview of the data. One approach is to portray the data in a *histogram,* **which is a bar graph that presents data from a frequency distribution.** Such a histogram, summarizing our TV viewing data, is presented in Figure **B.1(b)**.

Another widely used method of portraying data graphically is the *frequency polygon—***a line figure used to present data from a frequency distribution.** **Figures B.1(c)** and **B.1(d)** show how our TV viewing data can be converted from a histogram to a frequency polygon. In both the bar graph and the line figure, the horizontal axis lists the possible scores and the vertical axis is used to indicate the frequency of each score. This use of the axes is nearly universal for frequency polygons, although sometimes it is reversed in histograms (the vertical axis lists possible scores, so the bars become horizontal).

Figure B.1
Graphing data. (a) Our raw data are tallied into a frequency distribution. (**b**) The same data are portrayed in a bar graph called a histogram. (**c**) A frequency polygon is plotted over the histogram. (**d**) The resultant frequency polygon is shown by itself.

Score	Tallies	Frequency
6	I	1
5	III	3
4	IIII	4
3	IIII	5
2	III	3
1	II	2
0	II	2

(a) Frequency distribution
(b) Histogram

(c) Conversion of histogram into frequency polygon

(d) Frequency polygon

Figure B.2

Measures of central tendency. Although the mean, median, and mode sometimes yield different results, they usually converge, as in the case of our TV viewing data.
```
0
0
1
1
2
2

5
5
5
6
60 ÷ 20 = 3.00      Mean (arithmetic average of
                    summed scores)
```

median is the score that falls in the center of a distribution, the *mean* is the arithmetic average of the scores, and the *mode* is the score that occurs most frequently.

All three measures of central tendency are calculated for our TV viewing data in **Figure B.2**. As you can see, in this set of data, the mean, median, and mode all turn out to be the same score, which is 3. Although our example in Chapter 2 emphasized that the mean, median, and mode can yield different estimates of central tendency, the correspondence among them seen in our TV viewing data is quite common. Lack of agreement usually occurs when a few extreme scores pull the mean away from the center of the distribution, as shown in **Figure B.3**. The curves plotted in **Figure B.3** are simply "smoothed out" frequency polygons based on data from many subjects. They show that when a distribution is symmetric, the measures of central tendency fall together, but this is not true in skewed or unbalanced distributions.

Figure B.3(b) shows a *negatively skewed distribution,* in which most scores pile up at the high end of the scale (the negative skew refers to the direction in which the curve's "tail" points). **A** *positively skewed distribution,* in which scores pile up at the low end of the scale, is shown in **Figure B.3(c)**. In both types of skewed distributions, a few extreme scores at one end pull the mean, and to a lesser degree the median, away from the mode. In these situations, the mean may be misleading and the median usually provides the best index of central tendency.

In any case, the measures of central tendency for our TV viewing data are reassuring, since they all agree and they fall reasonably close to national estimates regarding how much young adults watch TV (Nielsen Media Research, 1998). Given the small size of our group, this agreement with national norms doesn't prove that our sample is rep-

Our graphs improve on the jumbled collection of scores that we started with, but *descriptive statistics,* which are used to organize and summarize data, provide some additional advantages. Let's see what the three measures of central tendency tell us about our data.

Measuring Central Tendency

PSYK TREK
1c

In examining a set of data, it's routine to ask "What is a typical score in the distribution?" For instance, in this case we might compare the average amount of TV watching in our sample to national estimates, to determine whether our subjects appear to be representative of the population. The three measures of central tendency—the median, the mean, and the mode—give us indications regarding the typical score in a data set. As explained in Chapter 2, **the**

Figure B.3

Measures of central tendency in skewed distributions. In a symmetrical distribution (**a**), the three measures of central tendency converge. However, in a negatively skewed distribution (**b**) or in a positively skewed distribution (**c**), the mean, median, and mode are pulled apart as shown here. Typically, in these situations the median provides the best index of central tendency.

(a) Symmetrical distribution

(b) Negatively skewed distribution

(c) Positively skewed distribution

resentative of the population, but at least there's no obvious reason to believe that it is unrepresentative.

Measuring Variability

Of course, the subjects in our sample did not report identical TV viewing habits. Virtually all data sets are characterized by some variability. *Variability refers to how much the scores tend to vary or depart from the mean score.* For example, the distribution of golf scores for a mediocre, erratic golfer would be characterized by high variability, while scores for an equally mediocre but consistent golfer would show less variability.

The *standard deviation is an index of the amount of variability in a set of data.* It reflects the dispersion of scores in a distribution. This principle is portrayed graphically in **Figure B.4**, where the two distributions of golf scores have the same mean but the upper one has less variability because the scores are "bunched up" in the center (for the consistent golfer). The distribution in **Figure B.4(b)**

is characterized by more variability, as the erratic golfer's scores are more spread out. This distribution will yield a higher standard deviation than the distribution in **Figure B.4(a)**.

The formula for calculating the standard deviation is shown in **Figure B.5**, where d stands for each score's deviation from the mean and Σ stands for summation. A step-by-step application of this formula to our TV viewing data, shown in **Figure B.5**, reveals that the standard deviation for our TV viewing data is 1.64. The standard deviation has a variety of uses. One of these uses will surface in the next section, where we discuss the normal distribution.

The Normal Distribution

The hypothesis in our study is that brighter students watch less TV than relatively dull students. To test this hypothesis, we're going to correlate TV viewing with SAT scores. But to make effective use of the SAT data, we need to understand what SAT scores mean, which brings us to the normal distribution.

The *normal distribution* is a symmetric, bell-shaped curve that represents the pattern in which many human characteristics are dispersed in the

(a)

(b)

Figure B.4

The standard deviation and dispersion of data. Although both these distributions of golf scores have the same mean, their standard deviations will be different. In (a) the scores are bunched together and there is less variability than in (b), yielding a lower standard deviation for the data in distribution (a).

TV viewing score (X)	Deviation from mean (d)	Deviation squared (d^2)
0	−3	9
0	−3	9
1	−2	4
1	−2	4
2	−1	1
2	−1	1
2	−1	1
3	0	0
3	0	0
3	0	0
3	0	0
3	0	0
4	+1	1
4	+1	1
4	+1	1
4	+1	1
5	+2	4
5	+2	4
5	+2	4
6	+3	9

$N = 20$

$\Sigma X = 60$ $\Sigma d^2 = 54$

$$\text{Mean} = \frac{\Sigma X}{N} = \frac{60}{20} = 3.0$$

$$\text{Standard deviation} = \sqrt{\frac{\Sigma d^2}{N}} = \sqrt{\frac{54}{20}}$$

$$= \sqrt{2.70} = 1.64$$

Figure B.5

Steps in calculating the standard deviation. (1) Add the scores (ΣX) and divide by the number of scores (N) to calculate the mean (which comes out to 3.0 in this case). (2) Calculate each score's deviation from the mean by subtracting the mean from each score (the results are shown in the second column). (3) Square these deviations from the mean and total the results to obtain (Σd^2) as shown in the third column. (4) Insert the numbers for N and Σd^2 into the formula for the standard deviation and compute the results.

population. A great many physical qualities (for example, height, nose length, and running speed) and psychological traits (intelligence, spatial reasoning ability, introversion) are distributed in a manner that closely resembles this bell-shaped curve. When a trait is normally distributed, most scores fall near the center of the distribution (the mean), and the number of scores gradually declines as one moves away from the center in either direction. The normal distribution is not a law of nature. It's a mathematical function, or theoretical curve, that approximates the way nature seems to operate.

The normal distribution is the bedrock of the scoring system for most psychological tests, including the SAT. As we discuss in Chapter 9, psychological tests are relative measures; they assess how people score on a trait in comparison to other people. The normal distribution gives us a precise way to measure how people stack up in comparison to each other. The scores under the normal curve are dispersed in a fixed pattern, with the standard deviation serving as the unit of measurement, as shown in **Figure B.6.** About 68% of the scores in the distribution fall within plus or minus 1 standard deviation of the mean, while 95% of the scores fall within plus or minus 2 standard deviations of the mean. Given this fixed pattern, if you know the mean and standard deviation of a normally distributed trait,

you can tell where any score falls in the distribution for the trait.

Although you may not have realized it, you probably have taken many tests in which the scoring system is based on the normal distribution. On the SAT, for instance, raw scores (the number of items correct on each subtest) are converted into standard scores that indicate where you fall in the normal distribution for the trait measured. In this conversion, the mean is set arbitrarily at 500 and the standard deviation at 100, as shown in **Figure B.7.** Therefore, a score of 400 on the SAT Critical Reading subtest means that you scored 1 standard deviation below the mean, while an SAT score of 600 indicates that you scored 1 standard deviation above the mean. Thus, SAT scores tell you how many standard deviations above or below the mean your score was. This system also provides the metric for IQ scales and many other types of psychological tests (see Chapter 9).

Test scores that place examinees in the normal distribution can always be converted to percentile scores, which are a little easier to interpret. A **percentile score** **indicates the percentage of people who score at or below the score you obtained.** For example, if you score at the 60th percentile, 60% of the people who take the test score the same or below you, while the remaining 40% score above you. There are tables available that permit us to convert any stan-

Figure B.6
The normal distribution.
Many characteristics are distributed in a pattern represented by this bell-shaped curve (each dot represents a case). The horizontal axis shows how far above or below the mean a score is (measured in plus or minus standard deviations). The vertical axis shows the number of cases obtaining each score. In a normal distribution, most cases fall near the center of the distribution, so that 68.26% of the cases fall within plus or minus 1 standard deviation of the mean. The number of cases gradually declines as one moves away from the mean in either direction, so that only 13.59% of the cases fall between 1 and 2 standard deviations above or below the mean, and even fewer cases (2.14%) fall between 2 and 3 standard deviations above or below the mean.
dard deviation placement in a normal distribution into a precise percentile score. **Figure B.6** gives some percentile conversions for the normal curve.

Of course, not all distributions are normal. As we saw in **Figure B.3**, some distributions are skewed in one direction or the other. As an example, consider what would happen if a classroom exam were much too easy or much too hard. If the test were too easy, scores would be bunched up at the high end of the scale, as in **Figure B.3(b)**. If the test were too hard, scores would be bunched up at the low end, as in **Figure B.3(c)**.

Measuring Correlation   1d

To determine whether TV viewing is related to SAT scores, we have to compute a *correlation coefficient*—a numerical index of the degree of relationship between two variables. As discussed in Chapter 2, a *positive* correlation means that two variables—say *X* and *Y*—co-vary in the *same* direction. This means that high scores on variable *X* are associated with high scores on variable *Y* and that low scores on *X* are associated with low scores on *Y*. A *negative* correlation indicates that two variables co-vary in the *opposite* direction. This means that people who score high on variable *X* tend to score low on variable *Y*, whereas those who score low on *X* tend to score high on *Y*. In our study, we hypothesized that as TV viewing increases, SAT scores will decrease, so we should expect a negative correlation between TV viewing and SAT scores.

The *magnitude* of a correlation coefficient indicates the *strength* of the association between two variables. This coefficient can vary between 0 and ±1.00. The coefficient is usually represented by the letter *r* (for example, *r* = .45). A coefficient near 0

tells us that there is no relationship between two variables. A coefficient of +1.00 or −1.00 indicates that there is a perfect, one-to-one correspondence between two variables. A perfect correlation is found only rarely when working with real data. The closer the coefficient is to either −1.00 or +1.00, the stronger the relationship is.

The direction and strength of correlations can be illustrated graphically in scatter diagrams (see **Figure B.8**). A *scatter diagram* is a graph in which paired *X* and *Y* scores for each subject are plotted as single points. **Figure B.8** shows scatter diagrams for positive correlations in the upper half and for negative correlations in the bottom half. A perfect positive correlation and a perfect negative correlation are shown on the far left. When a correlation is perfect, the data points in the scatter diagram fall exactly in a straight line. However, positive and negative correlations yield lines slanted in the opposite direction because the lines map out opposite types of associations. Moving to the right in **Figure B.8**, you can see what happens when the magnitude of a

Figure B.7
The normal distribution and SAT scores. The normal distribution is the basis for the scoring system on many standardized tests. For example, on the SAT, the mean is set at 500 and the standard deviation at 100. Hence, an SAT score tells you how many standard deviations above or below the mean you scored. For example, a score of 700 means you scored 2 standard deviations above the mean.

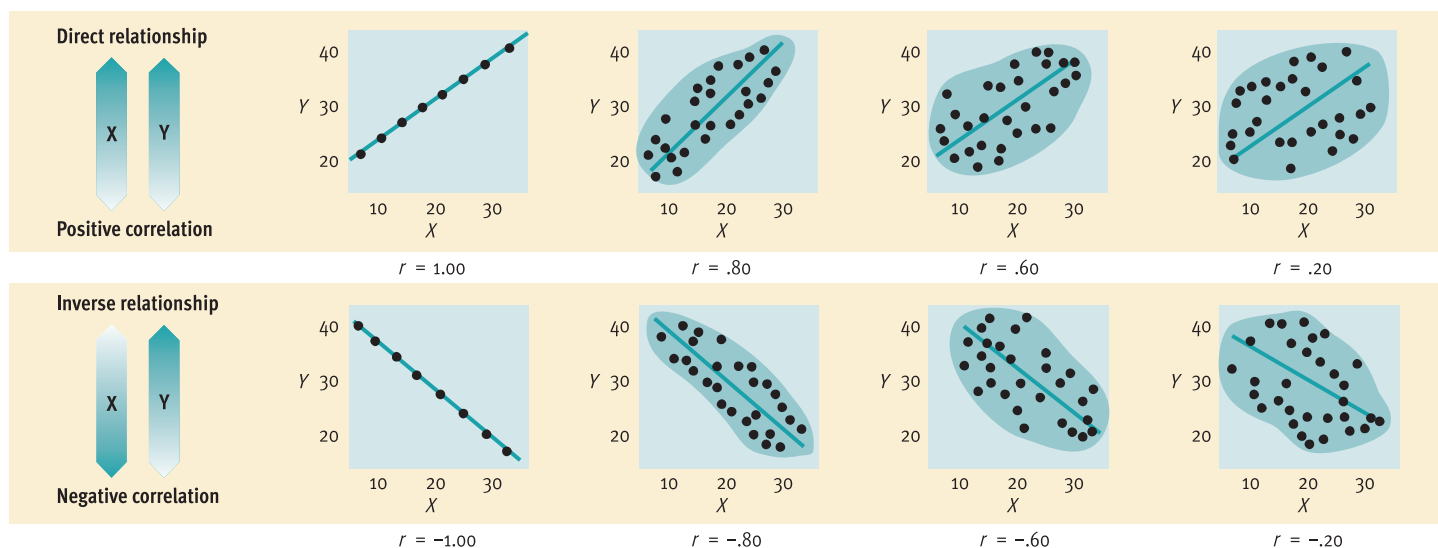
Figure B.8
Scatter diagrams of positive and negative correlations. Scatter diagrams plot paired *X* and *Y* scores as single points. Score plots slanted in the opposite direction result from positive (top row) as opposed to negative (bottom row) correlations. Moving across both rows (to the right), you can see that progressively weaker correlations result in more and more scattered plots of data points.


Figure B.9

Scatter diagram of the correlation between TV viewing and SAT scores. Our hypothetical data relating TV viewing to SAT scores are plotted in this scatter diagram. Compare it to the scatter diagrams seen in **Figure B.8** and see whether you can estimate the correlation between TV viewing and SAT scores in our data (see the text for the answer).
correlation decreases. The data points scatter farther and farther from the straight line that would represent a perfect relationship.

What about our data relating TV viewing to SAT scores? **Figure B.9** shows a scatter diagram of these data. Having just learned about scatter diagrams, perhaps you can estimate the magnitude of the correlation between TV viewing and SAT scores. The scat-

ter diagram of our data looks a lot like the one seen in the bottom right corner of **Figure B.8**, suggesting that the correlation will be in the vicinity of $-.20$.

The formula for computing the most widely used measure of correlation—the Pearson product-moment correlation—is shown in **Figure B.10**, along with the calculations for our data on TV viewing and SAT scores. The data yield a correlation of $r = -.24$. This coefficient of correlation reveals that we have found a weak inverse association between TV viewing and performance on the SAT. Among our participants, as TV viewing increases, SAT scores decrease, but the trend isn't very strong. We can get a better idea of how strong this correlation is by examining its predictive power.

Correlation and Prediction   1d

As the magnitude of a correlation increases (gets closer to either -1.00 or $+1.00$), our ability to predict one variable based on knowledge of the other variable steadily increases. This relationship between the

Figure B.10

Computing a correlation coefficient. The calculations required to compute the Pearson product-moment coefficient of correlation are shown here. The formula looks intimidating, but it's just a matter of filling in the figures taken from the sums of the columns shown above the formula.

Subject number	TV viewing score (X)	X^2	SAT score (Y)	Y^2	XY
1	0	0	500	250,000	0
2	0	0	515	265,225	0
3	1	1	450	202,500	450
4	1	1	650	422,500	650
5	2	4	400	160,000	800
6	2	4	675	455,625	1350
7	2	4	425	180,625	850
8	3	9	400	160,000	1200
9	3	9	450	202,500	1350
10	3	9	500	250,000	1500
11	3	9	550	302,500	1650
12	3	9	600	360,000	1800
13	4	16	400	160,000	1600
14	4	16	425	180,625	1700
15	4	16	475	225,625	1900
16	4	16	525	275,625	2100
17	5	25	400	160,000	2000
18	5	25	450	202,500	2250
19	5	25	475	225,625	2375
20	6	36	550	302,500	3300
$N = 20$	$\Sigma X = 60$	$\Sigma X^2 = 234$	$\Sigma Y = 9815$	$\Sigma Y^2 = 4,943,975$	$\Sigma XY = 28,825$

Formula for Pearson product-moment correlation coefficient

$$r = \frac{(N)\,\Sigma XY - (\Sigma X)(\Sigma Y)}{\sqrt{[(N)\,\Sigma X^2 - (\Sigma X)^2][(N)\,\Sigma Y^2 - (\Sigma Y)^2]}}$$

$$= \frac{(20)(28,825) - (60)(9815)}{\sqrt{[(20)(234) - (60)^2][(20)(4,943,975) - (9815)^2]}}$$

$$= \frac{-12,400}{\sqrt{[1080][2,545,275]}}$$

$$= -.237$$

magnitude of a correlation and predictability can be quantified precisely. All we have to do is square the correlation coefficient (multiply it by itself) and this gives us the *coefficient of determination,* **the percentage of variation in one variable that can be predicted based on the other variable.** Thus, a correlation of .70 yields a coefficient of determination of .49 (.70 × .70 = .49), indicating that variable *X* can account for 49% of the variation in variable *Y.* **Figure B.11** shows how the coefficient of determination goes up as the magnitude of a correlation increases.

Unfortunately, a correlation of .24 doesn't give us much predictive power. We can account only for a little over 6% of the variation in variable *Y.* So, if we tried to predict individuals' SAT scores based on how much TV they watched, our predictions wouldn't be very accurate. Although a low correlation doesn't have much practical, predictive utility, it may still have theoretical value. Just knowing that there is a relationship between two variables can be theoretically interesting. However, we haven't yet addressed the question of whether our observed correlation is strong enough to support our hypothesis that there is a relationship between TV viewing and SAT scores. To make this judgment, we have to turn to *inferential statistics* and the process of hypothesis testing.

Hypothesis Testing

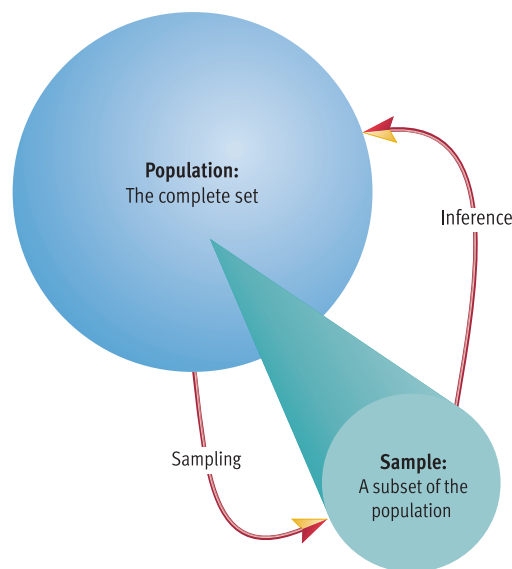
Inferential statistics go beyond the mere description of data. *Inferential statistics* **are used to interpret data and draw conclusions.** They permit researchers to decide whether their data support their hypotheses.

In Chapter 2, we showed how inferential statistics can be used to evaluate the results of an experiment; the same process can be applied to correlational data. In our study of TV viewing we hypothesized that we would find an inverse relationship between amount of TV watched and SAT scores. Sure enough, that's what we found. However, we have to ask ourselves a critical question: Is this observed correlation large enough to support our hypothesis, or might a correlation of this size have occurred by chance?

We have to ask a similar question nearly every time we conduct a study. Why? Because we are working only with a sample. In research, we observe a limited *sample* (in this case, 20 participants) to draw conclusions about a much larger *population* (college students in general). There's always a possibility that if we drew a different sample from the population, the results might be different. Perhaps our results are unique to our sample and not generalizable to the larger population. If we were able to collect data on the entire population, we would not have to wrestle with this problem, but our dependence on a sample necessitates the use of inferential statistics to precisely evaluate the likelihood that our results are due to chance factors in sampling. Thus, inferential statistics are the key to making the inferential leap from the sample to the population (see **Figure B.12** on the next page).

Although it may seem backward, in hypothesis testing we formally test the *null hypothesis*. As applied to correlational data, the **null hypothesis is the assumption that there is no true relationship between the variables observed.** In our study, the null hypothesis is that there is no genuine association between TV viewing and SAT scores. We want to determine whether our results will permit us to *reject* the null hypothesis and thus conclude that our *research hypothesis* (that there *is* a relationship between

Negative correlation   Positive correlation
Figure B.11
Correlation and the coefficient of determination.
The coefficient of determination is an index of a correlation's predictive power. As you can see, whether positive or negative, stronger correlations yield greater predictive power.

Figure B.12
**The relationship be-
tween the population
and the sample.** In
research, we are usually
interested in a broad popu-
lation, but we can observe
only a small sample from the
population. After making
observations of our sample,
we draw inferences about
the population, based on
the sample. This inferential
process works well as long
as the sample is reason-
ably representative of the
population.


the variables) has been supported. Why do we di-
rectly test the null hypothesis instead of the research
hypothesis? Because our probability calculations
depend on assumptions tied to the null hypothesis.
Specifically, we compute the probability of obtaining
the results that we have observed if the null hypoth-
esis is indeed true. The calculation of this probability
hinges on a number of factors. A key factor is the
amount of variability in the data, which is why the
standard deviation is an important statistic.

Statistical Significance

When we reject the null hypothesis, we conclude
that we have found *statistically significant* results.
Statistical significance is said to exist when the prob-
ability that the observed findings are due to chance
is very low, usually less than 5 chances in 100. This
means that if the null hypothesis is correct and we
conduct our study 100 times, drawing a new sample
from the population each time, we will get results
such as those observed only 5 times out of 100. If our
calculations allow us to reject the null hypothesis,
we conclude that our results support our research hy-
pothesis. Thus, statistically significant results typi-
cally are findings that *support* a research hypothesis.

The requirement that there be less than 5 chances
in 100 that research results are due to chance is the
minimum requirement for statistical significance.

When this requirement is met, we say the results are
significant at the .05 level. If researchers calculate
that there is less than 1 chance in 100 that their re-
sults are due to chance factors in sampling, the re-
sults are significant at the .01 level. If there is less
than a 1 in 1000 chance that findings are attribut-
able to sampling error, the results are significant at
the .001 level. Thus, there are several levels of signif-
icance that you may see cited in scientific articles.

Because we are only dealing in matters of prob-
ability, there is always the possibility that our deci-
sion to accept or reject the null hypothesis is wrong.
The various significance levels indicate the probabil-
ity of erroneously rejecting the null hypothesis (and
inaccurately accepting the research hypothesis). At
the .05 level of significance, there are 5 chances in
100 that we have made a mistake when we conclude
that our results support our hypothesis, and at the
.01 level of significance the chance of an erroneous
conclusion is 1 in 100. Although researchers hold
the probability of this type of error quite low, the
probability is never zero. This is one of the reasons
that competently executed studies of the same ques-
tion can yield contradictory findings. The differ-
ences may be due to chance variations in sampling
that can't be prevented.

What do we find when we evaluate our data link-
ing TV viewing to students' SAT scores? The calcula-
tions indicate that, given our sample size and the
variability in our data, the probability of obtaining
a correlation of −.24 by chance is greater than 20%.
That's not a high probability, but it's *not* low enough
to reject the null hypothesis. Thus, our findings are
not strong enough to allow us to conclude that we
have supported our hypothesis.

Statistics and Empiricism

In summary, conclusions based on empirical re-
search are a matter of probability, and there's al-
ways a possibility that the conclusions are wrong.
However, two major strengths of the empirical ap-
proach are its precision and its intolerance of error.
Scientists can give you precise estimates of the likeli-
hood that their conclusions are wrong, and because
they're intolerant of error, they hold this probability
extremely low. It's their reliance on statistics that al-
lows them to accomplish these goals.

Industrial/Organizational Psychology

by Kathy A. Hanisch (Iowa State University)

You have applied for a job, submitted your résumé and taken a series of tests. You have been interviewed by your potential supervisor and given a tour of the company. You now find yourself sitting across from the co-owners, who have just offered you a position. They tell you that their organization is a great place to work. As evidence, they tell you that no one has quit their job in the last five years and that employees are rarely absent. They also tell you that they have flexible policies. You can work whatever hours you like and take vacation whenever you want. And if you decide to work for them, you will have access to spending cash as well as keys to the company.

You try to maintain your composure. You had heard interesting things about this company but didn't really believe them. Finally, the co-owners ask you what you are worth, indicating they will pay you whatever you wish. Now you're really dumbfounded and wonder what the catch is but sit quietly while they talk about other issues. Does this sound too good to be true? Wouldn't this be ideal?

Almost this exact scenario played out in an organization owned and managed by an Oakland appliance dealer in the 1970s. His name was Arthur Friedman, and he had decided to change how he ran his business. Friedman, as reported in the *Washington Post* (Koughan, 1975), announced at one of his staff meetings that employees could work the hours they wanted, be paid what they thought they were worth, take vacation time and time off from work whenever they wanted, and help themselves to petty cash if they were in need of spending money. New employees would be allowed to set their own wages too. As you might imagine, the employees weren't sure how to take this news. It was reported that no one said anything during the meeting when Friedman first described his plan (Koughan, 1975).

When asked why he was changing his business practices, Friedman replied, "I always said that if you give people what they want, you get what you want. You have to be willing to lose, to stick your neck out. I finally decided that the time had come to practice what I preached" (Koughan, 1975). In the final analysis, Friedman's experiment worked. The organization was profitable. Friedman signed union contracts without reading them (the employees didn't need a union with him in charge). Employees didn't quit, they didn't steal from the company, and they were rarely absent. Net profits increased, and the company was a success. The employees realized that to make the organization work and remain in business, they had to be reasonable in their requests and behavior (Koughan, 1975).

A more recent company with some extra benefits for employees is Google, headquartered in Mountain View, California (the heart of Silicon Valley). In 2007, *Fortune* magazine rated it the number one company to work for. Included among its many perks are free gourmet meals, snack rooms, free haircuts, gyms, massages, subsidized exercise classes, classes to learn another language, child care, on-site doctors for free employee checkups, a pet-friendly facility, and a traveling library for book checkout. In addition, Google offers free shuttlebus transportation to work or, if the employee drives, free on-site car washes and oil changes. When an employee has a baby, Google provides up to $500 reimbursement for takeout food to ease the transition home. If an employee refers a friend to work at Google and the friend is hired, the referring employee gets a cash bonus. Google even provides washers and dryers so employees can do their laundry at work for free (the detergent is provided, too!). In addition to all these benefits, Google rewards innovation, both high-tech and otherwise, and allow employees such as engineers to spend some of their time at work on independent projects.

Google provides many employee perks, including free meals and haircuts, exercise classes, game rooms, child care, and on-site doctors. Would you want to work for Google?

Organizations such as Google and Friedman's company are interesting in the way they deal with their employees and in the ways such treatment affects their employees' behaviors. Psychologists who study people's behavior at work are called *industrial and organizational psychologists*. **Industrial and organizational (I/O) psychology is the branch of psychology concerned with human behavior in the work environment.** I/O psychologists assist organizations in important areas such as motivating employees, alleviating job stress, hiring the best workers, and combating safety problems. Work is an important avenue of study for psychology because of its link to the health of the American economy, as well as people's feelings of self-worth and well-being. I/O psychologists study employee selection, performance appraisal, training, job design, communication, work stress, motivation, leadership, groups and teams, organizational culture, human factors, job attitudes, well-being, and work behavior. This appendix will introduce you to the field of I/O psychology.

The Role of Work in People's Lives

You have learned about work since you were a small child. You may have asked where your mother was going when she took you to day care or why your father left the house before 8 A.M. and did not return until after 5 P.M. You likely "played" at different jobs by dressing up as an astronaut, firefighter, teacher,

The Doctor is In! Socialization about the nature and importance of work begins very early in life.

Courtesy of Kathy Hanisch

chef, or construction worker. As you got older, other sources of information about work may have come from your friends, other family members, school, and the media. In high school, more education and a part-time job may have given you additional details about the meaning of work. As you pursue a college degree, you may receive information about the work and jobs available in your chosen field through classes, internships, or other job experiences.

Work is an important part of life for most people. We often ask people we meet what they "do," which translates into "What is your job and for whom do you work?" Many people identify with their work because they spend so much of their waking lives at work. Work is important because it provides many of the things people need and value. Work for pay provides the money necessary to satisfy people's basic needs for food, shelter, and security (health care, retirement income), while the "leftover" money provides discretionary funds to use as one sees fit. These funds can go toward a round of golf, an iPod, or a fancy place to live; can go to support charities or attend athletic or fine art performances; or to save money for college. Essentially, money, typically from work, provides people with a standard of living that depends on their income and how they choose to spend it. And work provides much more: a source of social interactions and friendships, independence, a sense of accomplishment, satisfaction, a reason to get up in the morning, happiness, a sense of identity, recognition, and varied amounts of prestige (see **Figure C.1**).

Although most researchers and practitioners agree that money and recognition are nearly universal motivators (Clark, 2003), what is valued or sought from work varies from person to person. For example, the prestige of a job may not be important to you but might be important to your best friend. Perhaps you want your work to provide you with a sense of accomplishment or a source of social interactions, while your friend simply sees it as a way to pay the bills. It is important to understand what you want from your work as well as what a job can provide.

From an employer's perspective, it is useful to determine what employees want because satisfied employees will be more likely than dissatisfied employees to work diligently to meet organizational goals. Part of a supervisor's job is to determine what employees value, because those values can be used to motivate employees to perform well in their jobs.

Types of Jobs

There are many types of work, in many types of jobs, in many organizational settings. These settings in-

clude multinational conglomerates; public and private companies; nonprofits; federal, state, and local government organizations; and home businesses.

People in the United States work a variety of schedules, from extended workweeks (45+ hours) to standard workweeks (35–44 hours) to part-time workweeks (less than 35 hours). Some workers, such as police officers, medical personnel, and factory workers, have work shifts other than the typical 8 A.M. to 5 P.M. Others are offered flexible working schedules that best fit their lives as long as they work the required number of hours and accomplish their work. Telecommuting is becoming more and more popular, because of advances in communication technologies. Regardless of the type of job or your work schedule, it is likely that you will spend most of your waking hours in some type of employment for many years. Many people spend their weekends working, too. Because work is critical to who you are and what you do, studying the psychological principles and some of the topics examined by I/O psychologists will provide you with information that may be useful to you in your future careers. Before focusing on the specific aspects of getting and keeping a job, let's briefly explore the subfields of I/O psychology and possible career paths in this area.

Subfields and Other Aspects of I/O Psychology

I/O psychology is made up of three specialty areas. I/O psychology consists primarily of the two areas that define its name: (1) *industrial (I) psychology,* and (2) *organizational (O) psychology*. The third area is known as *human factors* or *human engineering psychology*. **Industrial psychology (also known as personnel psychology) deals with the how-to side of I/O psychology, including how to select individuals for the right positions, how to evaluate their job performance, how to train them, and how to compensate them.** This is the oldest of the three subfields. The broad areas of job analysis, job evaluation, test validation, employee selection (including interviewing), employee training, legal issues including employment discrimination in the organization, and performance evaluation are included in this subfield. **Organizational psychology is concerned with how employees are integrated into the work environment from both emotional and social perspectives.** Some of the areas covered include job satisfaction, job stress, work motivation, leadership, organizational culture, teamwork, and organizational development. Although not included in the field's name, human factors psychology is also an important specialization within I/O psychology.

Jobs with the Highest and Lowest Prestige		
	Job description	Percent rating job as high prestige
Highest prestige	Firefighter	63%
	Doctor	58%
	Nurse	55%
	Scientist	54%
	Teacher	52%*
Lowest prestige	Stockbroker	11%
	Business executive	11%
	Real estate broker/agent	6%

*The prestige ratings for teachers rose from 29% in 1977 to 52% in 2006, the only job surveyed to show a positive change in prestige over 29 years.

Figure C.1
Variations in job prestige. Among other things, jobs vary in the prestige that they convey. This chart lists a few examples of jobs that possess either high prestige or low prestige, based on a 2006 survey.

Human factors (or *human engineering*) *psychology examines the ways in which work, systems, and system features can be designed or changed to most effectively correspond with the capabilities and limitations of individuals, often with a focus on the human body.* Examples of issues in this area include redesigning machines to be easier on the systemic aspects of the body, changing the positions of controls on machines to reduce the number of accidents, modifying displays so that the user can quickly determine the information presented, and making the job more interesting by increasing the types of skills needed to perform the work. All three areas—industrial psychology, organizational psychology, and human factors psychology—are interrelated when addressing problems or issues in the world of business and industry.

Most I/O psychologists have graduate degrees that typically require an additional two to five years of school beyond the bachelor's degree. I/O psychologists obtain jobs primarily in four work settings: industry, academia, consulting firms, and government, with the largest percentage in industry and academia. Figure C.2 on the next page provides examples of typical job postings for I/O psychologists taken from recent recruitment ads for each of the four areas.

In the United States, a fairly recent advance of relevance to the I/O field is the development of the *Occupational Information Network (O*NET)*. The O*NET is a comprehensive, detailed, and flexible set of job descriptors based on an extensive research program (Peterson et al., 1999), which can be accessed via the Internet. O*NET can be used to find details about occupations (for example, tasks, knowledge, skills, work activities, wages, employment outlook) or to select preferred work activities or interests and locate corresponding occupations. It is a helpful starting point for individuals seeking details about the types of occupations that may interest them as well as the salary and occupational outlook for various

Academic position	Industry position	Consulting position	Government position
The Department of Psychological Sciences at Purdue University is excited to invite applicants to apply for a tenure track position in Industrial/Organizational Psychology at the beginning or advanced Assistant Professor level beginning in the Fall. For this position the successful candidate will have a strong publication history, the beginnings of a strong research program with the likelihood of future funding, as well as a record of teaching excellence.	GEICO, a Berkshire Hathaway company and the fastest growing auto insurer in the country, is seeking a senior manager to lead our Selection Systems group in its corporate headquarters in Chevy Chase, Maryland (just outside of Washington, DC). The position reports directly to the Corporate Vice President of Staff Development.	AutoZone, a Fortune 500 company is seeking an experienced, innovative Organization Development Consultant at our Memphis Store Support Center. This position will be responsible for improving and executing core Organization Development processes (e.g., performance management, talent and succession planning, and employee development) and for performance improvement consulting with business leaders to drive solutions to business issues in an environment of substantial growth and rapid change.	Immediate opening for a psycholgist (YA-180-02) at the Center for Army Leadership, Fort Leavenworth, KS. Applicants should be prepared to conduct research using principles, theories and findings from leadership, organizational behavior, experimental psychology, and social psychology, and to conduct training to enhance leaders' performance and combat readiness. Immediate research areas include cross-cultural influence, leadership development, and competency measurement.

Figure C.2
Recruitment advertisements for I/O psychologists. Abbreviated versions of recent ads for positions available for individuals with I/O psychology degrees are shown here. The industry position prefers an individual with a master's degree, whereas the other three positions require or prefer a Ph.D.

occupations. It is also useful to employers who need to develop thorough job descriptions for their organizations. Although there have been some concerns about its coverage and information, O*NET is viewed as a major achievement in occupational information (Sackett & Laczo, 2003). Information continues to be updated and added to the O*NET. According to O*NET, the projected growth for I/O psychologists of 21% for 2006–2016 is much faster than average.

The Society for Industrial and Organizational Psychology (SIOP) is the primary professional organization for I/O psychologists. There are approximately 6000 members, including individuals from academia, industry, consulting positions, and the government. The SIOP website is a great resource for information about graduate school, jobs, and articles in I/O psychology.

Selecting Employees

One of the most important tasks for any business enterprise is to select talented, motivated employees who will work hard to help the organization meet its goals. As you will see in this section, the task of employee selection is complicated and must be handled with sensitivity and fairness.

The Hiring Process

In the early 1900s, when someone needed a job he or she would hang around the outside of a company and wait to see whether the company needed workers. Many times the people who worked for the company told their friends or relatives about possible job openings, prompting them to apply for work. This often meant that individuals hired for the available jobs were similar to those working there (such as white males). Industrial and organizational psychologists first became involved in the process of selecting employees when the United States government needed help selecting and placing officers and soldiers in World War I (Aamodt, 2007). They used

mental ability tests to determine who would become officers and who would be assigned to the infantry.

The process many employers use now to hire employees is very detailed, typically consisting of five components: job analysis, testing, legal issues, recruitment, and the selection decision.

Job Analysis

Job analysis is a method for breaking a job into its constituent parts. It is a process used to identify the most important parts of the job. I/O psychologists have helped devise effective strategies for determining three basic aspects of any job: (1) What tasks and behaviors are essential to the job? (2) What knowledge, skills, and abilities are needed to perform the job? and (3) What are the conditions (such as stress, safety, and temperature) under which the job is performed? A job analysis can be conducted in many ways. An analyst may interview current employees, have them complete questionnaires, observe people in the job, or talk to people knowledgeable about the job (Gael, 1988).

I/O psychologists continue to research effective job analysis techniques. Current research suggests that worker-oriented methods are best for employee selection (Aamodt, 2007) because of their focus on the worker as opposed to the tasks. One worker-oriented method is the Critical Incident Technique (CIT), which uses critical incidents or behaviors that discriminate between excellent and poor behavior for someone performing the job (Flanagan, 1954). For example, excellent behavior for a university professor might involve lecturing about relevant material beyond what is covered in the textbook (Aamodt, 2007).

The information from a job analysis is used in many types of personnel functions. including employee selection, performance appraisal, training, and human resources planning. Within the hiring process, job analysis is used to write job descriptions; to determine what tests might be used to as-

sess the relevant knowledge, skills, and abilities of job applicants; and to assist in meeting legal requirements that affect the selection process.

Testing and Other Employee Selection Procedures

The next step in personnel selection is assessing whether job candidates have the attributes required for specific jobs that are available. Employers use quite a variety of employee selection tools, including individual and panel interviews, standardized paper-and-pencil tests of abilities and knowledge, assessments of personality traits, such as conscientiousness, and honesty tests. In addition, work samples, in which applicants do a replica of the work they will be asked to do on the job, can be useful. Reference checks, Internet searches, and drug testing are also used to help find top-flight employees. Selection procedures that are properly developed and carefully used are vital to the success of organizations.

Psychological testing has long played an important role in employee selection efforts. As noted in Chapter 9, a *psychological test is a standardized measure of a sample of a person's behavior.* Employers can purchase tests from commercial test publishers or can develop special tests to meet their own needs. Early on in the process of using a test, it behooves organizations to assess the *reliability* and *validity* of the test, as discussed in Chapter 9. *Reliability refers to the measurement consistency of a test (or of other kinds of measurement techniques).* Reliable tests yield consistent results over the course of multiple testings. *Validity refers to the ability of a test to measure what it was designed to measure.* Evidence regarding validity is crucial when tests are used for employee selection purposes. When an organization purchases a commercial test for use, the information about reliability and validity is normally provided by the test publisher.

Once a suitable test has been found or developed, the next step is to administer it to job candidates and decide which of them has the greatest probability of being successful on the job. Justifying the use of psychological tests in hiring people depends on collecting data that demonstrates a relationship between test scores and performance on the job. In a simple scenario the scores achieved on a test by job applicants are compared to their job performance ratings or evaluations some time after being hired (such as six months or one year). These comparisons can be used to calculate a correlation coefficient that will indicate how strong the relation is between the test scores and job performance. The ideal relationship would be a strong positive correlation that would in-

dicate that as tests score improve, job performance ratings improve and, alternatively, as tests score decrease, job performance decreases. A graph illustrating this type of relationship is shown in **Figure C.3**.

Personality testing appears quite frequently in employers' selection processes. One type of personality test being used by many organizations is the integrity test. *Integrity tests are standardized measures used to assess attitudes and experiences related to honesty and trustworthiness.* Employers want to be able to use these tests to help them choose applicants who are dependable, honest, and trustworthy. Research indicates that integrity tests are reliable and scores are related to theft, absenteeism, and performance (Aamodt, 2007). Use of these tests in hiring has also led to a reduction in compensation claims (Sturman & Sherwyn, 2007).

Although standardized mental ability and personality tests are commonly used in personnel selection, the most widely used device remains the interview. Nearly all organizations use some type of employee interview in their selection process (Salgado, Viswesvaran, & Ones, 2003). There are two broad types of interviews: unstructured and structured (see **Figure C.4** on the next page). *Unstructured interviews* are informal: Job candidates are asked different questions with no scoring key, and there is no method for assigning scores to applicants. Although many employers rely heavily on this type of interview, research suggests that it is highly subjective and does not provide very reliable or useful information in the selection of employees (Aamodt, 2007). *Structured interviews* are more like standardized tests. The same questions are asked of all candidates by a trained interviewer and are based on attributes

Figure C.3
A hypothetical example of the relationship between test scores and job performance. When a standardized test is used to select the most promising job candidates, the expectation is that higher scores on the test will be associated with better performance on the job. The relationship won't be perfect, but when employers look at the relationship between test scores and subsequent performance ratings, the findings should resemble the hypothetical data shown here. These data would yield a very strong positive correlation between test scores and job performance, indicating the test is a good predictor of job performance.

Figure C.4

Structured versus unstructured interviews. Structured interviews can yield very different kinds of information than unstructured interviews. These examples of typical interview questions can give you some idea of how the two types of interviews differ.

necessary for success on the job in question (based on the job analysis). There are clear guidelines for judging the adequacy of the answers given, and the scores assigned to an applicant have known relationships to the attributes being measured. Structured interviews can be constructed to be reliable and valid (McDaniel et al., 1994). In addition, they hold the promise of supplying useful information *not* supplied by psychological testing (about characteristics such as oral comprehension, communication and listening skills, and motivation).

Legal Issues

One of the most important pieces of legislation regarding employment, and specifically the hiring of employees, is Title VII of the Civil Rights Act of 1964 (Equal Employment Opportunity Commission, 2002). Title VII "prohibits discrimination based on race, color, religion, sex, and national origin," referred to in some quarters as the "Big 5." Providing protection based on the Big 5 helps ensure that all applicants have an equal opportunity for employment. Exceptions to this provision include matters of national security, employers with seniority systems in place, and *bona fide occupational qualifications (BFOQs).* BFOQs permit organizations to discriminate in hiring persons in a protected class if the qualification is determined to be reasonably necessary to the operation of the business. For example, women can be discriminated against when hiring someone to model men's swimwear, and vice versa. It is reasonably necessary to the marketing and selling of swimwear that organizations hire men to model male swimwear and women to model female swimwear; sex is a thus a BFOQ in this case. It is not

reasonably necessary, however, that a secretary in a church who does secretarial work and not church or religious work be the same religion as the church that employs him or her; religion could not be used as a BFOQ in this case.

It is important for employers to abide by laws that protect people against discrimination, as the costs of litigation can be very high, in terms of both financial costs and the organization's reputation. This situation applies to discrimination based not only on the Big 5, covered under the Civil Rights Act, but also on age (Age Discrimination in Employment Act) and disability (Americans with Disabilities Act). Employment law in the United States is meant to protect and provide equal opportunities for all individuals.

There are differences among countries with regard to fair employment practices, laws, and what is considered discriminatory in the employment setting. The United States has several acts that prohibit discrimination based on a number of group characteristics. Other countries allow what would be considered discrimination in the United States. For instance, the advertisement shown in **Figure C.5** for a position in Thailand would not be legal in the United States. It specifies that the applicant must be male, which would be illegal under Title VII. It also specifies an age range of 26–28, which would be il-

What would happen to this advertisement if the model were male? Sex is a BFOQ in this case.

legal in most states. U.S. federal law prohibits age discrimination once a person reaches the age of 40 (Age Discrimination in Employment Act). It is likely that females and those older than 28 and perhaps even younger than 26 could perform just as well in the job of sales engineer.

Nondiscriminatory hiring practices attempt to guarantee fair treatment for any person looking for a job. In the United States, organizations with several employees (typically 15) are required to abide by the employment laws. Equal opportunity laws make the job market a more level playing field in the United States than in many countries.

Recruitment

Recruitment is the process organizations use to identify potential employees for a job. Depending on the job, an organization may recruit from inside the company or seek someone outside the organization. Openings may be advertised on the company's website or on a site for specific types of jobs. In addition, websites such as monster.com, hotjobs.com, and careerbuilder.com link potential employees and employers in a variety of jobs and locations. Other recruitment sources include newspapers, radio and television advertisements, trade magazines, professional publications, and employee referrals.

Research indicates that employees recruited through *inside sources,* such as employee referrals, tend to hold their jobs longer and to exhibit better job performance than those recruited through *outside sources,* such as advertisements, employment agencies, and recruiters (Zottoli & Wanous, 2000). Studies have supported the idea that those recruited using inside sources receive more accurate information about the job (a realistic job preview) than those recruited through external sources (Conrad & Ashworth, 1986; McManus & Baratta, 1992). Research also shows that employees who stay with the organization longer typically were referred by successful employees rather than unsuccessful employees (Aamodt & Rupert, 1990).

A survey of the 50 best small and medium organizations to work for in the United States found that 92% use employee referrals. The survey also found that more than 30 percent of all hires were referred by a current employee (Pomeroy, 2005). Because of the effectiveness of employee referrals, some companies provide rewards to employees who recommend an applicant who is hired. These rewards can include cash, vacations, and raffles for prizes such as televisions and free maid service for a year (Stewart et al., 1990). Typically, the new employee must work for the organization a set period of time for the referring employee to receive the award (Stewart et al., 1990).

☐ **Sales Engineer**

Post Date :	Friday, September 05, 2008	Location :	Srinakarin Road
Salary :	20-25,000		
Business Type :	Trading : equipment & machinery		

Qualifications: -Male, age 26-28 years old
-Degree in Mechanical, Electrical Engineering or related field
-At least 2 years experience in sales function for equipment or machinery
-Knowledge in technical support and troubleshooting
-Human relations, service-minded and good negotiation skills
-Good command of English and PC skill
-Own car with driving license

Job description: -All daily sales activities of company in terms of visiting customers, meetings for
requirements and coordinating with customers & concerned parties, etc.

SOURCE: http://www.pasona.co.th/en/hotjob.aspx

Figure C.5
Culture and employment laws. The laws governing fairness and equal opportunity in hiring vary from one country to another. This advertisement for a position in Thailand would not be legal in the United States because the unnecessary specifications regarding applicants' gender and age would violate the Civil Rights Act and the Age Discrimination in Employment Act.

Google rewards employees with a $2,000 bonus if their referral accepts Google's offer and remains employed for at least 60 days (Google, 2008).

After applicants have submitted either a résumé or an application, someone from the organization such as the human resources manager or supervisor will determine which applicants should be considered further. In that process, he or she may make telephone inquiries of previous employers or other references and conduct criminal background checks to alleviate potential legal problems as well as to hire appropriate personnel. Reference checks can help organizations avoid costly errors when hiring employees. For instance, one company unknowingly hired someone who had just gotten out of jail and was on parole in another state (and was not supposed to leave the state). Upon finding out about the parole violation, the hiring company also found out that the new employee had been in jail for stealing from his previous employer. These types of hiring mistakes can often be avoided by conducting reference and background checks on job applicants.

Internet searches focusing on job applicants' background are becoming more common because of advances in technology and the ease with which employers can learn about potential employees before hiring them. Employers are searching social networking sites such as MySpace and Facebook to learn about job applicants. On these sites, recruiters and companies have found promising candidates reporting on their drug use, sexual exploits, and drinking, along with suggestive photographs (Finder, 2006). As you might guess, these indiscretions are considered "red flags" by employers. Companies generally assume that these applicants are lacking in good judgment and typically remove them from their selection process (Finder, 2006). Information that students thought would only be viewed by their peers is making its way into the public arena at all

levels, with future employers and relatives viewing the information without the students' knowledge.

Making the Hiring Decision

When selecting employees, employers are looking for a good match between the employee and the organization. They would like to match the requirements for excellent job performance with the person's own knowledge, skills, abilities, personality, and motivation. They attempt to accomplish this by using the various selection tools discussed earlier.

Researchers have posited two factors that determine an employee's performance in a job: the "can-do" and the "will-do" factors (Schmitt et al., 2003). *Can-do factors* suggest what employees are capable of doing on the job if they are working to the best of their ability. *Will-do factors* suggest the time and effort employees are willing to exert for the organization. Personality factors such as conscientiousness and need for achievement as well as integrity have been classified as important will-do factors in performance (Schmitt et al., 2003). A person's can-do and will-do factors may change as he or she moves from organization to organization. Once a person is selected, the important process of being accepted and socialized into the organization at all levels begins.

Socializing Employees: Culture, Groups, and Leadership

When you report for your first day of work in an organization, you will need to learn many things in order to be successful in your job. ***Organizational socialization* refers to the process by which new members are absorbed into the culture of an organization** (Jablin, 1982). Organizational socialization consists of people learning how the organization operates by using information provided by management, co-workers, observation, and company handbooks or memos.

Nowadays, electronic communication is an important part of how workers are socialized (Flanagin & Waldeck, 2004). Employees communicate through e-mail, company websites, chat groups, and blogs. Job applicants may also use these resources to learn about an organization before submitting their applications. Consulting business websites is an excellent way for job applicants to assess whether there might be a good fit between them and an organization.

Supervisors and co-workers are also important sources of socialization information. ***Mentoring* is a form of training in which a current and often long-term employee (the mentor) is paired with a new employee to aid his or her growth and development within the organization.** The mentor's role is to help the new employee adapt to the job by assisting with advice or resources. The mentor may provide information about how the organization works and about career advancement opportunities. Good mentoring helps new employees become successful on the job and learn the formal and informal rules of the organization (Aamodt, 2007).

Research indicates that both mentors and those they mentor often benefit from the relationship. For example, in one study of health care employees, it was found that those who were mentored reported higher salaries, greater promotion rates, and more positive career success than those who did not receive mentoring (Allen, Lentz, & Day, 2006). Employees who have been mentored experience more effective socialization and better compensation, advancement, career satisfaction, job satisfaction, job involvement, and organizational commitment than those with no mentoring (Greenhaus, 2003).

Organizational Culture and Climate

***Organizational culture* refers to the shared assumptions, beliefs, values, and customs of the people in an organization.** These cognitions then influence the *organizational climate,* which consists of employees' shared perceptions about specific aspects of the workplace environment. Because culture and climate generally operate in concert, our discussion will refer to these elements collectively as *culture* (Ostroff, Kinicki, & Tamkins, 2003). Organizational culture is important because it lets employees know what is expected of them and affects how they think and behave. Culture is often shaped by the founders of the organization, but it may be modified over time by other influential leaders and by the successes and failures of the organization.

There have been several case studies of organizations that have successfully changed their culture. Remember Arthur Friedman from the beginning of this appendix? He allowed his employees to set their own wages and decide the hours they worked; he also required employees to belong to the union. After Friedman made these changes, employee grum-

bling stopped. The organizational culture changed, resulting in better morale, increased productivity, and longer employee tenure. No one wanted to quit working in a culture where the employees got to make their own decisions that affected the organization's bottom line. Finding an organizational culture that fits your working style is likely to have consequences for your morale, performance, and tenure in the organization.

Work Teams

Work teams and the leadership of an organization tend to have great influence on the culture of an organization. Groups have been studied by social psychologists for more than 75 years (e.g., Hare, 1962; McGrath, 1966). Research has focused on group dynamics topics such as individual versus group problem solving (Hill, 1982; Paulus, 2000) and the effects of participation in decision making on members' satisfaction and performance (Likert, 1967; Sagie, 1997). Industrial and organizational psychologists have focused on studying groups or teams in organizations. The use of teams or groups in organizations has been increasing in recent years because work is now being increasingly organized around team-based structures instead of individual jobs (Lawler, Mohrman, & Ledford, 1995).

Many college courses have assignments that require students to work in groups, and students are graded as a group instead of as individuals. Do you like to work on projects in a group? Do you put in as much effort as you would if you were completing the assignment alone? Among other benefits, students working in groups gain insights into group dynamics, develop their interpersonal skills, and are exposed to other viewpoints (Mello, 1993). Students with less experience with group assignments and grading tend to support group grading; older students are less satisfied with a group experience than younger students; and students who work part-time view the group grading experience as more positive than do those who work full-time (Barfield, 2003). The odds are good that you will find yourself in groups in college classrooms that will prepare you for the almost inevitable work teams in your future.

Work teams, or *work groups,* **can be defined as two or more employees who have common goals, pursue tasks that are interdependent, interact socially, and work within specific requirements and rules** (Kozlowski & Bell, 2003). Just as an organization can have its own culture, groups or teams exhibit subcultures that may encourage or discourage certain types of work-related behaviors and attitudes. These subcultures then form the basis for the socialization of new group or team members.
"I don't know how it started, either. All I know is that it's part of our corporate culture."

Virtual work teams are becoming more commonplace in the workforce because of the desire to involve employees with specific talents on projects and because of the globalization of many businesses. Virtual work teams can continue to function when members work from home, are away traveling, or are otherwise outside of the traditional office (Wiesenfeld, Raghuram, & Garud, 2001). Virtual work teams typically meet using some type of electronic technology. For example, they may communicate by e-mail or teleconferencing. Virtual work teams have a number of advantages. They can provide a way for groups to collaborate more effectively and less expensively, they often reduce office space requirements if individuals

Virtual work teams, where team members interact using teleconferencing and email to get their work accomplished, have become more commonplace in the last decade because of advances in technology.

can work from home, and they permit more flexibility for employees dealing with personal problems or long commutes.

Although most organizations provide formal means of socializing new employees, the dynamics and norms of a work team may have informal but substantial effects on employees' socialization (Anderson & Thomas, 1996). Of course, the outcomes of informal and formal socialization processes may be different. Work teams may have appointed leaders or they may be self-managing. When teams fail, the failure is often linked to the team leader. Team leaders may be too autocratic, wielding too much power or influence. As a result, the team does not realize the autonomy and control it needs to be successful (Stewart & Manz, 1995). Self-managing teams tend to show better productivity, an increase in work quality, improved quality of life for employees, decreased absenteeism, and decreased turnover (Cohen & Ledford, 1994).

Developing a work team may mean successfully integrating new employees into the team as well as helping with the transition of individuals into and out of the team, depending on the team's function. Team leaders are critical to the success of work teams' newcomers. Establishing and maintaining conditions wherein the team can perform well is also an important role for the team leader.

Leadership

Former U.S. President Dwight D. Eisenhower once said, "Leadership is the art of getting someone else to do something you want done because he wants to do it." As his remark suggests, *leadership* **involves influencing and motivating people to pursue organizational goals.**

Oprah Winfrey is a modern-day charismatic, transformational leader. She is probably best known as the host of the Oprah Winfrey Show. *In addition, she has built a multi-faceted entertainment empire and started multiple charity groups, donating millions of dollars across the globe.*

© Peter Kramer/Getty Images

Leadership has received a lot of research attention in industrial and organizational psychology. Many theories exist, and most have been helpful in understanding what makes a good leader and how to improve leadership style.

Personality plays a key role in many leadership theories. Certainly, it is important in determining whether or not a leader will be successful. Kirkpatrick and Locke's (1991) review suggests that drive, honesty and integrity, self-confidence, cognitive abilities, and knowledge are associated with successful leaders. Leaders with poor cognitive abilities and social skills and those who are indecisive, low in self-confidence and self-esteem, dishonest, and lacking in ambition tend to be less successful (Kaplan, Drath, & Kofodimos, 1991).

Arthur Friedman's integrity likely made him a successful leader. He decided to give employees what he would want, providing them with the capability to make major decisions that could either make or break the organization. In his case, he created a self-managing group that had no need for external assistance from unions or other entities. As a result, Friedman demonstrated the transformational leadership approach (Bass, 1990). *Transformational leadership* **is characterized by high ethical standards, inspirational motivation, intellectual stimulation, and individual consideration**—all clearly evident in Arthur Friedman's leadership style.

Leaders today must contend with information-based team environments requiring the capacity for sifting through large amounts of information coming from computer networks (Avolio, Kahai, & Dodge, 2000). The widely varying working environments that result from global competition also require leaders to be adaptable (Mann, 1959), capable of handling stress (Goleman, 1998), knowledgeable about competitors and products (Kirpatrick & Locke, 1991), and able to solve complex problems quickly (Zaccaro et al., 2000).

Training and Human Factors

Employers hope that the applicants they choose for positions in their organization will be great workers who are dependable and have good attitudes. However, sometimes a poor fit between the employee and the job indicates that some type of change may be needed in the employee, the job, or some specific aspect of the job. Trying to change the employee to better fit the job or work that needs to be done involves *training,* while changing the job to better fit the employee is a *human factors issue.* Both of these areas are of importance to organizations, and both

types of changes can help organizations maximize job performance.

The premise behind training is that it will lead to learning that will in turn lead to an improvement in job performance. Important questions to address before conducting training include (1) What are the goals of the training program? (2) Who needs the training and for what purpose? and (3) What should the content of the training program be? The goals of the training program will likely come from the training department or human resources department. Whatever the specific goals are for the organization, support from top management is critical for training to be a success. Deciding who needs training is relatively simple if an effective performance evaluation system is in place in the organization. Accurate and valid performance evaluation procedures can provide valuable information on who needs additional training.

Many types of training are available, including both on-the-job and off-the-job programs. On-the-job training includes job rotation, mentoring (discussed earlier), and apprenticeships, while off-the-job training is the typical lecture or taped presentation. All of these can be effective under the right circumstances, so the training needs to be tailored to the employees who would benefit the most. Some of the important issues with regard to training include setting specific, concrete, and obtainable goals, and motivating employees to attend the training and transfer it to their jobs (Aamodt, 2007). It is vital that the training program be evaluated to determine whether it is effective in changing behavior or improving performance and whether the cost is worth the results. All organizations must engage in some type of training for their employees, from orientation meetings to sessions on how to use a new software package or new machine.

As noted earlier, *human factors psychology* examines the ways in which work, systems, and system features can be designed to most effectively correspond with the capabilities and limitations of workers. In other words, human factors is concerned with changing the system, in this case the work, the work environment, or the job itself, so that employees' interactions with the system are better from a psychological, emotional, or physical standpoint. An important subfield of human factors work is *ergonomics,* which focuses on the capabilities and limitations of the human body. For example, if the desk chair that a computer programmer is using causes her back problems because the seat height can't be adjusted, she can be given a new chair with adjustable seat height. Or if a receptionist is not motivated because his work lacks variety, the work could be en-

Human factors psychology plays an important role in the design of all sorts of equipment, ranging from consumer products to industrial machines.

Courtesy of NIOSH Pittsburgh Research Laboratory

riched or changed so that more skills could be used in the job. Human factors focuses on changing the system to better fit the employee using the system. This may be a critical issue if problems are found with employees' behaviors and attitudes in an organization. Redesigning a job or equipment can sometimes be the key to enhancing performance.

Attitudes and Behaviors at Work

One of the most important factors influencing whether people will be motivated to do a good job hinges on their attitudes at work. The causes and consequences of work attitudes have been extensively researched. Some of the determinants of work attitudes include job security issues, the type of work (e.g, interesting or boring), and pay and promotion issues. Job attitudes can influence many important outcomes in the world of work, such as whether employees volunteer for projects or help out co-workers, whether employees are frequently tardy or absent, and whether they think about quitting or early retirement.

Attitudes at Work

Attitudes at work include commitment to the organization and satisfaction with such job aspects as the work itself, pay and benefits, supervision, co-workers, promotion opportunities, working conditions, and job security. In general, you can be satisfied or dissatisfied with the tasks and conditions at work, the people in your work environment, and the rewards you get from work. Employee satisfaction is important because it has been shown to be related to employee behaviors at work (Hanisch, 1995). Job satisfaction and organizational commitment are two of the most commonly studied work attitudes.

Job satisfaction **consists of the positive or negative emotions associated with a job** (Thurstone,

1931). In other words, job satisfaction reflects how much employees like or dislike their work. Some of the ways organizations can create satisfied employees include offering flexible working hours, professional growth opportunities, interesting work (Hackman & Oldham, 1976), autonomy, job security, a good supervisor, good benefits, competitive pay, and opportunities for promotion (Cranny, Smith, & Stone, 1992). What makes one worker satisfied may not make another worker satisfied. For some people, interesting work is paramount. Others place higher emphasis on having co-workers they like. Still others feel that the pay and benefits they receive are most important. Just as in the hiring process, a match between what you want and what the organization can provide will result in a more successful outcome for both parties.

Some organizations take the emotional temperature of their employees by periodically administering questionnaires. These questionnaires typically ask workers to rate their levels of satisfaction on the basic factors that contribute to job satisfaction. An example of a measure of job satisfaction can be seen in **Figure C.6**. Organizations go to the trouble of gathering this information because they believe (and research supports) that job satisfaction is related to employee withdrawal behaviors such as absenteeism and turnover (Hanisch, 1995).

A recent survey found that listening to music at work leads to higher levels of reported employee satisfaction. About one-third of those participating in a Spherion Workplace Snapshot survey conducted by Harris Interactive in 2006 reported they listened to an iPod, MP3 player, or other personal music device while working (Spherion, 2006). More than three-fourths of the participants reported that listening to music improved their job satisfaction and productivity at work. Allowing workers to listen to music may become more and more popular in jobs where music does not interfere with co-workers, safety, or job performance. Having happy workers contributes to an organization's success.

Employee commitment to an organization is related to employee retention within the organization. According to Meyer and Allen (1991) there are three types of organizational commitment: affective, normative, and continuance. *Affective commitment* consists of an employee's emotional attachment to the organization, which makes the employee want to stay in the organization. *Normative commitment* is

Figure C.6
The Work on Present Job Scale. One measure often used to assess employee work attitudes and specific facets of job satisfaction is the Job Descriptive Index (JDI) originally published by Smith, Kendall, and Hulin (1969). This index, which has been improved based on years of research (Balzer et al., 1997; Hanisch, 1992), measures five facets of job satisfaction. The five subscales assess satisfaction with: the work itself, supervisors, co-workers, present pay, and opportunities for promotion. The most frequently used subscale is the one shown here, which measures satisfaction with the work itself.

Work on Present Job Scale
Think of the work you do at present. How well does each of the following words or phrases describe your job? In the blank beside each word or phrase below, write:

Y for "Yes"if it describes your work
N for "No"if it does NOT describe it
? if you cannot decide

_____ 1. Fascinating
_____ 2. Routine
_____ 3. Satisfying
_____ 4. Boring
_____ 5. Good
_____ 6. Creative
_____ 7. Respected
_____ 8. Uncomfortable
_____ 9. Pleasant
_____ 10. Useful
_____ 11. Tiring
_____ 12. Healthful
_____ 13. Challenging
_____ 14. Too much to do
_____ 15. Frustrating
_____ 16. Simple
_____ 17. Repetitive
_____ 18. Gives sense of accomplishment

Scoring Key:

1. Y=3, N=0, ?=1	7. Y=3, N=0, ?=1	13. Y=3, N=0, ?=1
2. Y=0, N=3, ?=1	8. Y=0, N=3, ?=1	14. Y=0, N=3, ?=1
3. Y=3, N=0, ?=1	9. Y=3, N=0, ?=1	15. Y=0, N=3, ?=1
4. Y=0, N=3, ?=1	10. Y=3, N=0, ?=1	16. Y=0, N=3, ?=1
5. Y=3, N=0, ?=1	11. Y=0, N=3, ?=1	17. Y=0, N=3, ?=1
6. Y=3, N=0, ?=1	12. Y=3, N=0, ?=1	18. Y=3, N=0, ?=1

To interpret your score on the this scale, 27 is considered the neutral value (Balzer, et al., 1997). Values considerably higher would be evaluated as very satisfied, values considerably lower would be evaluated as very dissatisfied with the work on your present job.
Employees report that their job satisfaction and productivity increase if they are allowed privileges such as listening to music while they work.

based on feelings of obligation to the organization. *Continuance commitment* results when an employee remains with a company because of the high cost of losing organizational membership, including monetary (pension benefits) and social (friendships) costs. Meyer and Herscovitch (2001) argue that employees have an organizational commitment profile at any given time in their job, with high or low values on each of the three types of commitment. In other words, an employee may have high scores on normative and continuance commitment but be lower on affective commitment. Depending on the profile, the employee may engage in different behaviors, such as quitting or helping out the organization.

Students may experience these different types of commitment to their college. A student acting under affective commitment would feel an emotional attachment to the school because she really likes it, including her classes, the football team, and the town. The student wants to stay in that school because of her attachment to it. Normative commitment might be evidenced by a student whose parents attended that college and who feels obligated to do the same thing regardless of whether it is the best school for him. Staying at a college because one's friends are there and one has already paid for two years of college would typify acting under continuance commitment.

One of the key factors in organizational commitment is job satisfaction. People who are satisfied with their job tend to be more committed to their organization than those who are less satisfied (Mueller et al., 1994). Other determinants of organizational commitment include trust in one's supervisor and human resources practices that are supportive of employees (Arthur, 1994). The organizational commitment of Arthur Friedman's employees was very high, as evidenced by a complete lack of turnover in five years.

Behaviors at Work

Employers want their employees to engage in behaviors that will make them successful in the job be-

"Employee morale is at an all-time high. We must be paying them too much."

cause employee success helps the organization meet its goals, including earning profits and fulfilling its mission. Employees have control over two aspects of their work—their time and their effort (Naylor, Pritchard, & Ilgen, 1980). Employees arriving at work on time instead of being late or absent is important to performance and productivity. Positive behaviors generally help an organization meet its goals, whereas negative behaviors make it harder to reach those goals.

Organizational citizenship behaviors (OCBs) are often described as extra-role behaviors because they are not specifically required by the job and are not usually evaluated during performance reviews. These behaviors go beyond what is formally expected by the organization (Smith, Organ, & Near, 1983). Examples include staying late to finish a project, mentoring a new employee, volunteering for work, and helping a co-worker. Some reasons why people engage in organizational citizenship behaviors are job satisfaction, high job autonomy, a positive organizational culture, high agreeableness (as a personality dimension; Witt et al., 2002), and high conscientiousness (Borman et al., 2001). Often, however, males who engage in OCBs are viewed positively, whereas females are viewed as just doing their jobs (Heilman & Chen, 2005; Kidder & Parks, 2001)—a difference that may result in gender disparities in performance ratings. OCBs have positive consequences for the organization and for employees in their day-to-day interactions with others in the organization.

You may engage in prosocial behaviors that are analogous to OCBs at your university—for instance, by helping a student in a class by tutoring him or allowing him to study with you. You may also exhibit these types of behaviors in your personal life by donating blood or being a Big Brother or Sister to a boy or girl who needs a positive role model. Altruism and prosocial behaviors are closely linked; they likely carry over into the work environment.

In contrast to OCBs, some unhappy employees cause problems for organizations because they engage in behaviors that researchers refer to as *organizational withdrawal* (Hanisch, Hulin, & Roznowski, 1998) and counterproductive behaviors (Sackett & DeVore, 2003). Organizational withdrawal consists of behaviors employees use to avoid their work (work withdrawal) or their job (job withdrawal) (Hanisch, 1995; Hanisch & Hulin, 1990, 1991). Examples of work withdrawal include being absent from work, leaving work early, arriving to work late, missing meetings, and using work equipment for personal use without permission. Examples of job withdrawal are quitting one's job, transferring to another department within an organization, and retiring.
College students may be familiar with withdrawal behaviors when it comes to certain college courses. Some classes may fail to keep your attention, and you may find yourself taking a nap in class or reading the newspaper. You may even look for legitimate reasons not to attend class, such as offering to fill in for another employee at work or deciding to attend an optional session for another class.

Counterproductive behaviors, although similar in some ways to withdrawal behaviors, are defined as "any intentional behavior on the part of an organizational member viewed by the organization as contrary to its legitimate interests" (Sackett & DeVore, 2003). An example of a counterproductive behavior would be an intentional violation of safety procedures that puts the employee and the organization at risk. Other examples of counterproductive behavior are theft, destruction of property, unsafe behavior, poor attendance, drug use, and inappropriate physical actions such as attacking a co-worker.

Relations Between Attitudes and Behaviors

Organizational citizenship behaviors are positively related to job satisfaction and organizational commitment. In other words, employees with good attitudes who feel committed to their organization are more likely to do positive things to assist the organization (LePine, Erez, & Johnson, 2002). Research indicates that those employees who demonstrate organizational citizenship behaviors are less likely to engage in counterproductive behaviors (Dalal, 2006). Researchers have found strong links between job satisfaction and specific withdrawal or counterproductive behaviors such as absenteeism (Hackett, 1989), and even stronger links with job withdrawal (Hanisch & Hulin, 1990).

Counterproductive behaviors may sometimes be an outcome of high job stress. In such cases, the counterproductive behaviors often represent dysfunctional coping mechanisms (Lennings, 1997). For example, an employee experiencing stress from having too much work to do might respond by being absent from work or by sabotaging work equipment.

Many years of research indicate a link between employees' attitudes and their behaviors at work. Sometimes the most revealing information about employees occurs when unforeseen circumstances arise and they then have to choose how to behave without concern for what a supervisor, co-workers, or their work team might think. An interesting study along these lines was conducted by Smith (1977) when he took advantage of inclement weather to study the relationship between job attitudes and job behaviors.

Smith compared functional work groups in Chicago, where a terrible snowstorm had occurred, to work groups in New York where the weather was fine. All employees worked for the same organization, and they had completed an organization-wide survey assessing work attitudes a few months earlier. Examining both organizational sites provided a comparison not typically available and allowed the researcher to examine the relationship between work attitudes and attendance under difficult circumstances. The comparison was done to determine which employees would opt to attend work the day after the storm in Chicago.

Correlational results indicated a positive relationship between work attitudes and attendance for the employees headquartered in Chicago; those reporting higher satisfaction were more likely than those with lower satisfaction to attend work. It was up to the discretion of the individuals in the Chicago sample whether to attend work the day after the storm; the correlational results suggest that those work groups with more positive attitudes made a greater effort to attend work that day than those with less positive attitudes. Interestingly, the relationship between work attitudes and attendance was not significant for the groups based in New York, where weather-related challenges were not an issue (see **Figure C.7**).

Employers need to evaluate their work environment and fringe benefit packages and make modi-

Correlations between job satisfaction and attendance in different weather conditions		
Job Satisfaction Scale	**Chicago**	**New York**
	(following severe storm)	(normal weather conditions)
Supervision	.54*	.12
Amount of work	.36*	.01
Kind of work	.37*	.06
Financial rewards	.46*	.11
Career future	.60*	.14
Company Identification	.42*	.02

* Statistically significant

Figure C.7

An example of the link between work attitudes and work behavior. Smith (1977) had an interesting opportunity to explore the link between job satisfaction and work behavior when a nasty snowstorm in Chicago made it difficult for employees to get to work. These data show the correlation between satisfaction with various aspects of work and the likelihood of job attendance following the severe storm. The correlations for similar workers in New York, where weather was not a problem that day, provide a control condition. As you can see, satisfied employees were much more likely to brave the elements and show up for work, illustrating the importance of work attitudes.

fications where necessary to ensure that they have employees who are satisfied and committed. Art Friedman made modifications in the work environment of his organization that resulted in high satisfaction and commitment among his employees. To help with the commute to and from work, Google added a free shuttle service that many employees say is the best fringe benefit, given the traffic in Silicon Valley (Helft, 2007). Employees need to learn how to seek out satisfying work and perks that will result in a sense of commitment to the organization. Satisfaction and commitment facilitate OCBs and decrease withdrawal and counterproductive behaviors. Together, the right employee attitudes and behaviors will lead to successful organizational functioning.

Integration of the Field

I/O psychologists grapple with issues related to the world of work from both the employee and employer perspectives. Moreover, the three subfields of I/O psychology are highly interrelated. I/O psychologists often have expertise in more than one subfield because in dealing with many organizational problems or concerns, information from two or more of the subfields may be necessary to effectively address the issue. For example, I was asked to be a consultant on a project for a large utility company because several instances of employee "near-misses" had occurred in a short time frame. In other words, employees had almost been severely hurt or killed as a result of accidents on the job. To address such a problem, I met with the safety and training directors to obtain a clear understanding of the equipment being used in the field (a human factors topic) as well as the types of training implemented to ensure a safe environment, including safety training (an industrial psychology topic). I also met with the personnel director to ascertain how employees were selected for the various positions in question regarding the safety violations (an industrial psychology topic). Finally, I administered an attitude survey to try to better understand employees' attitudes toward their work, the organizational climate for safety, and behaviors with a specific focus on withdrawal, counterproductive, and safety behaviors (an organizational psychology topic). Any one or a combination of two or three of these issues could have been causing the safety problems. The results of my investigation indicated there were problems with safety attitudes and training as well as with work attitudes in general. A specific finding from my research was that even though the employees were encouraged to engage in safe behaviors by management, they were simultaneously being told to work faster, with greater emphasis being placed (albeit unknowingly) on working faster. Employees also had suggestions for ways to improve the equipment they used to be more effective in their jobs. An integration and understanding of the many areas that could impinge on organizational issues or problems aids in finding an appropriate solution to them.

Conclusion

In this appendix a consistent theme has been that appropriate matches between people's characteristics and their jobs are important for both employees and employers. A good match can help ensure that you enjoy and are successful in the job, while at the same time ensuring that the organization is a success in terms of its bottom line regarding performance and costs. The first type of match that is important is the correspondence between your knowledge, skills, ability, and personality, and the needs of the job you are applying for. This match is important because you don't want to be bored if the job doesn't use your skills or overstressed if the job requires an ability you do not have. Just as it is important for an organization to hire the right person, it is important for you to find the right employer and the right position for your talents. Another crucial match is between an employer's organizational climate and your preferred organizational culture (friendly versus aloof, supportive versus competitive). Again, those who run the organization desire a good match so that you will be a productive employee; your satisfaction and commitment to the organization will be higher within a culture that fits your personality. Finally, the reason these matches are important is that an organization must be profitable, and that requires dedicated and effective employees. Happy, productive employees will likely lead to a profitable venture for both employees and those who manage or own organizations. I/O psychologists have been critical in facilitating these matches for mutually beneficial relations between employees and employers for many decades, and they will continue to play a vital role in these matching processes in the future.

Careers and Areas in Psychology

by Margaret A. Lloyd (Georgia Southern University)

Perhaps you have already heard the disheartening claim, "You can't get a job with a bachelor's degree in psychology." Is there any truth to this assertion? If by "job," you mean working as a professional psychologist, then the saying is true. Psychologists must have a doctoral degree in psychology because the nature of their work requires more extensive education and training than can be gained at the undergraduate level. But it simply is *not* true that you can't get a good entry-level job with a psychology degree.

In the following pages, we will briefly explore the kinds of entry-level jobs that are available to psychology majors as well as some occupations that require graduate degrees. I will also share some pointers to help you compete effectively in the job market and to enhance your chances of getting into graduate school.

Entry-Level Career Options for Psychology Majors

It would be easy to spot entry-level jobs if you could look in the want ads under the heading "psychologist," but as already noted, that tactic won't work. Because the connection between the psychology major (and other liberal arts majors) and relevant entry-level jobs is not as obvious as it is in applied majors (nursing and accounting, for example), identifying relevant entry-level jobs requires some detective work.

Thanks to the Internet, it has become easier to identify job titles of interest. A number of websites have search engines that allow you to locate specific occupations and learn about the relevant skills, educational requirements, salaries, and other useful points (see Web Links D.2, D.3, and D.4).

Because most psychology majors would like jobs in which they can help other people, *counseling* is a popular career option. If you think about it, though, there are many other ways to help people. For example, managers help employees to do their best, child welfare agents help children in trouble, and probation officers help juvenile offenders stay on the right track. Also, in doing your detective work, you should be aware that occupations requiring essentially the same skills are often listed under a variety of titles. Don't overlook a viable option because the title is unfamiliar. **Figure D.1** will give you an idea of the wide range of job options open to psychology majors.

Once you have identified some occupations of interest, compare them on the critical factors of current job openings, salary, and future employment outlook. An excellent resource for this information is the *Occupational Outlook Handbook* (see Web Link D.2). This step is essential if you want to make *informed* occupational choices.

The average starting salary for psychology (and other liberal arts) majors tends to be lower than for most applied majors. In 2007-2008, it was around $30,000 (National Association of Colleges and Employers, 2008). Jobs in business and research com-

Figure D.1
Entry-level positions open to psychology majors. A bachelor's degree in psychology can prepare students for a diverse array of entry-level jobs in a variety of occupational areas. The jobs listed here are merely a handful of examples of the entry-level positions for which psychology majors qualify.

Potential Jobs for Psychology Majors with a Bachelor's Degree	
Business area	**Health and human services areas**
customer relations	behavioral analyst
employment interviewer	case worker
human resources recruiter	child welfare agent
insurance agent	director of volunteer services
loan officer	drug counselor
management trainee	family services worker
marketing representative	hospital patient service representative
realtor	nursing home administrator
sales representative	rehabilitation advisor
store manager	residential youth counselor
Law and corrections areas	**Other areas**
case manager	affirmative action officer
corrections officer	college admissions representative
court officer	newspaper reporter
EPA investigator	research assistant
probation/parole officer	technical writer

mand higher salaries than those in human services (counseling and social work, for example). If you are like most students, however, your job decision will not be based on money alone. A recent survey regarding what college graduates seek when choosing an employer found that "a high starting salary" was ranked surprisingly low, whereas "enjoying what I do" earned the top ranking (National Association of Colleges and Employers, 2005). Thus, salary is just one of many factors that you should consider in pursuing a job.

Keys to Success in the Entry-Level Job Market

There are three keys to a successful job search. First, you need to have accurate information about the knowledge, skills, and values required for occupations that interest you. You may be surprised to learn that these skills and values are not as job-specific as most people assume. Surveys of employers reveal that a relatively small set of skills and values are considered essential for success in wide variety of occupations (see **Figure D.2**). You don't have to be a genius to figure out the second key to success: You need to acquire these skills that are prized by employers. The third key to a successful job search is to assemble convincing documentation for prospective employers that you possess these skills and values.

Developing Valuable Skills

To help you acquire these highly rated work skills, you have three excellent skill-building vehicles available: college courses, relevant work experience, and extracurricular activities. Obviously, the earlier in your college career you start your "skills development project," the more time you have to hone your skills.

College courses. Within the constraints of curriculum requirements, choose courses to help you develop occupationally relevant knowledge and skills. Make thoughtful choices across all areas of the curriculum: general education courses, psychology courses, and general electives. The content of courses is an obvious and important aspect of education. Your coursework also provides learning opportunities that are less obvious. In addition to teaching course content, college courses provide numerous opportunities to learn a remarkable variety of skills that can give you a competitive edge in the job market. For example, your courses can help you improve your critical thinking skills, acquire insights into your behavior and that of others, enhance your interpersonal skills, clarify your values, acquaint you with ethical principles, improve your communication abilities, increase your computer sophistication and information literacy, and bolster your self-management skills (setting and completing goals, managing your time, coping with stress). The

General Work Skills and Personal Values Employers Seek

Work skills

- **Communication skills.** Almost always rated first, communication skills include being able to write and speak effectively. A third, often overlooked, communication skill is effective listening, including being sensitive enough to hear and relate to the emotions behind another's words.

- **Adaptability/flexibility.** Employers value workers who can adapt to changing conditions and work assignments (learn new skills), deal with ambiguity, and appreciate that there are usually several legitimate perspectives on an issue.

- **Analytical/research skills.** These important skills involve critical thinking; extracting key ideas from written material, graphs, and tables; and solving problems and answering questions.

- **Computer skills.** Employers want workers who are competent in using word-processing, spread-sheet, and database management programs, as well as the Internet and e-mail.

- **Social and teamwork skills.** Today's workers need to interact effectively in one-on-one settings and on teams. They must also be able to work well with co-workers from diverse cultures and backgrounds.

- **Self-management skills.** These critical skills include having self-confidence, being able to work with little supervision, being able to set manageable goals and complete them on time, and being able to manage time effectively. Emotional maturity is also important, especially the ability to cope with undesirable behavior in others and to refrain from petty behavior.

Personal values

- **Integrity/honesty.** Employers greatly value ethical behavior in their employees.

- **Dependability and loyalty.** Workers who come to the workplace prepared to work, who arrive on time, and who show up every day are prized. Employers also value personal and company loyalty in their employees.

- **Positive attitude and motivation/energy.** Valued employees are those who have a "can-do" attitude, bring energy to their work, and are willing to learn new skills and information.

Figure D.2
Qualities employers value in employees.
Employers widely agree on the general work skills and values they desire in employees. To be competitive in the job market, workers must have the qualities listed here and document them in cover letters, résumés, and interviews. (Based on Appleby, 2000; Hansen & Hansen, 2003; Landrum & Harrold, 2003)

psychology major can definitely help you develop the general skills and values that employers seek. **Figure D.3** lists ten learning goals that a psychology major should support, based on the consensus of a national task force. If you compare this list with the list of employers' preferred skills and values in **Figure D.2**, you will see that there is a close match.

Relevant work experience (internships, paid work, and volunteer activities). If you must work while attending school, look for a job that will help you develop useful skills. For example, if you want to be a probation officer, seek out volunteer opportunities to work with adolescents. Many colleges have Volunteer Services offices that match students' interests with community needs. Another excellent resource on how to obtain real-world experience is a short paperback, *Getting from College to Career: 90 Things to Do Before You Join the Real World* (Pollak, 2007). The author, a recent college graduate, offers useful and specific advice on how to shape your college experience to give you a "jump start" on your career.

Extracurricular activities. Involvement in campus clubs and student activities can also help you develop work-related abilities—especially leadership and interpersonal skills. Be careful not to overload yourself with work, volunteering, and extracurricular activities to the detriment of your grades. Good grades are important in obtaining your first job and getting good recommendations from faculty members, and they are *essential* to qualify for graduate school.

Documenting Your Skills

Once you acquire the skills and values employers want, you must be able to document this fact to prospective employers. You do so by preparing résumés and cover letters that showcase your skills. The job interview is another key aspect of this process. Even if you have a bundle of talents, you can easily falter at these critical points. There is a lot to know in developing a competitive résumé, a compelling cover letter, and good interviewing skills. You can learn the essentials at your Career Services office.

Next Steps

It is critical that you start the job search process early—the spring term of your senior year is too late. Attend career fairs, where job recruiters come to your college campus, to learn about job options and what recruiters are looking for. When you are clear about the occupational titles you want to pursue, visit your Career Services office. The staff can get you started off right on your job search.

Career Options at the Master's Level

After working several years in an entry-level position, you may want more challenges, a higher salary, or greater independence. One way to move up the career ladder is to return to school. Alternatively, you may want to attend graduate school directly upon graduation. If you want to extend your knowledge and skills, but do not want to invest the time, effort, and money required for a doctoral degree, then a master's degree may be just the ticket for you. Because counseling is a popular career option among psychology majors, we will focus on three master's-level career options in the mental health area. There are also master's-level careers in other areas of psychology, such as industrial/organizational psychology. An undergraduate major in psychology is excellent preparation for all these career paths.

Clinical Psychology

Clinical psychologists diagnose and treat people with psychological problems and administer psychological tests. Although most programs in clinical

---

Learning Goals for the Psychology Major
Knowledge, skills, and values consistent with the science and application of psychology
Goal 1. Knowledge base of psychology. Students should show familiarity with the major concepts, theoretical perspectives, empirical findings, and historical trends in psychology.
Goal 2. Research methods in psychology. Students should understand and apply basic research methods in psychology, including research design, data analysis, and interpretation.
Goal 3. Critical thinking skills in psychology. Students should respect and use critical and creative thinking, skeptical inquiry, and, when possible, the scientific approach to solve problems related to behavior and mental processes.
Goal 4. Application of psychology. Students should understand and apply psychological principles to personal, social, and organizational issues.
Goal 5. Values in psychology. Students should be able to weigh evidence, tolerate ambiguity, act ethically, and reflect other values that are the underpinnings of psychology as a discipline.
Knowledge, skills, and values consistent with liberal arts education that are further developed in psychology
Goal 6. Information and technological literacy. Students should demonstrate information competence and the ability to use computers and other technology for many purposes.
Goal 7. Communication skills. Students should be able to communicate effectively in a variety of formats.
Goal 8. Sociocultural and international awareness. Students should recognize, understand, and respect the complexity of sociocultural and international diversity.
Goal 9. Personal development. Students should develop insight into their own and others' behavior and mental processes and apply effective strategies for self-management and self-improvement.
Goal 10. Career planning and development. Students should emerge from the major with realistic ideas about how to implement their psychological knowledge, skills, and values in occupational pursuits in a variety of settings.

Figure D.3

Knowledge, skills, and values supported by the psychology major. Ten learning goals for the undergraduate psychology major have been outlined by a national task force (American Psychological Association, 2007). The first five goals include knowledge, skills, and values developed specifically in the psychology major. The remaining goals consist of knowledge, skills, and values developed in the liberal arts (general education) curriculum and that psychology further advances.

SOURCE: American Psychological Association. (2007). *APA guidelines for the undergraduate psychology major.* Washington, DC: Author. Retrieved May 1, 2008, from http://www.apa.org/ed/psymajor_guideline.pdf.

psychology are offered at the doctoral level, there are terminal master's degree programs in clinical psychology and some other subfields. Clinical master's programs typically teach students how to administer selected psychological tests as well as the basics of psychological diagnosis and psychotherapy. Students in these programs receive either an M.A. (Master of Arts) or an M.S. (Master of Science) degree. Upon graduation, they either seek employment or apply to doctoral programs.

Some states license individuals with master's degrees in clinical psychology, but many do not. A license is a quality-control credential that gives individuals legal authority to work independently—that is, without the supervision of a doctoral-level professional. Individuals with a master's degree in clinical psychology may qualify for licenses such as "psychological associate," "professional counselor," or "marriage and family therapist." Note that they are not licensed as "psychologists"—this title is reserved for those with doctoral degrees. Whether licensed or not, these individuals are qualified to work in supervised settings such as community mental health centers.

Clinical Social Work

Unlike social workers or case workers, *clinical social workers* diagnose and treat psychological problems. Clinical social workers are educated in departments or colleges of social work (not psychology departments). The degree that they earn is the M.S.W. (Master of Social Work). They do not do psychological testing, so you should consider majoring in psychology or education if you want to do assessment. They work in community mental health centers, counseling centers, hospitals, and schools. Importantly, all 50 states license clinical social workers at the master's level. This fact makes clinical social work an attractive career option. For more information, see Web Link D.7.

Agency Counseling

Agency counselors provide various types of counseling assistance to clients and may administer a limited number of psychological tests (occupational interest tests, for example). Thus, the work is somewhat like that done by those with a master's degree in clinical psychology. Counselors are educated in departments of education; they receive the M.Ed. (Master of Education) degree. Most people assume that a degree in education requires one to work in a school setting. Agency counseling (sometimes called "community counseling") is an important exception. If you want to counsel but do not want to work in a school setting, consider this option. Graduates typically work in community mental health centers.

They may have a private practice if they obtain a license (typically as a "professional counselor" or "marriage and family therapist").

Career Options at the Doctoral Level

Doctoral-level education and training will give you access to occupations that offer more options and independence as well as higher salaries, compared to those at the master's level. An important consideration is whether you want to emphasize teaching and research or applied work.

Teaching and Research Versus Applied Work

If you want to teach in a university setting, you will probably also be expected to conduct research. If you want to focus solely on teaching, consider a job at a two-year college, as research is not usually required in these institutions. If you are solely interested in doing research, think about working for government agencies (for example, the Centers for Disease Control) or private organizations (for example, the Educational Testing Service). To work in a university psychology department, you will need a Ph.D. (Doctor of Philosophy) in psychology—not a degree in another field such as education or social work. As discussed in Chapter 1, the major research subfields in psychology include cognitive psychology, developmental psychology, educational psychology, experimental psychology, health psychology, personality psychology, physiological psychology, psychometrics, and social psychology. We will discuss some career options in these areas shortly.

In certain subfields, psychologists are qualified to apply their knowledge by offering professional services to the public. These applied areas of specialization include clinical psychology, counseling psychology, industrial/organizational psychology, school psychology, clinical neuropsychology, and forensic psychology. The required degree for most of these areas is typically the Ph.D. (Doctor of Philosophy). The Psy.D. (Doctor of Psychology) is also appropriate in clinical and counseling psychology, and the Ed.D. (Doctor of Education) is awarded in counseling psychology. We will examine career options in these applied areas shortly.

Before looking at the various specialty areas, let's touch on the differences between the Ph.D. and Psy.D. degrees, as students often have questions about this issue. The Ph.D. degree is the terminal (highest) degree offered in all liberal arts and scientific disciplines (psychology, history, physics, and so forth). Thus, the vast majority of college and university professors have the Ph.D. degree. The Psy.D.

degree is awarded *only* in psychology and *only* in the professional areas of clinical and counseling psychology—not in other applied areas such as school psychology or industrial/organizational psychology, nor in any of the research subfields (experimental, developmental, or social psychology, for example). The primary difference between the two degrees is the emphasis on research. The Ph.D. degree prepares clinical and counseling psychologists to be both researchers and practitioners. In contrast, Psy.D. programs focus exclusively on preparing clinicians and counselors to be practitioners, although they also strive to make their students highly sophisticated consumers of psychological research. The crux of the difference is that Ph.D. students are required to conduct research to earn their degree, whereas Psy.D. students are not. This means that Ph.D. students typically take a number of courses in research design and statistics and devote much of their time to research projects. Psy.D. programs, on the other hand, tend to require students to spend more time in "hands-on" clinical training.

Another distinction concerns the types of institutions in which the programs are housed. Ph.D. programs in psychology are housed in traditional university psychology departments (as are a few Psy.D. programs), whereas most Psy.D. programs are housed in private, independent, professional schools of psychology. One practical repercussion of this difference is that university-based Ph.D. programs tend to benefit from research grants that permit them to offer many of their students tuition waivers and financial stipends that can greatly reduce the financial cost of graduate training. Lacking this source of revenue, Psy.D. programs are generally able to provide far less financial aid and thus tend to be more expensive than Ph.D. programs. Both types of doctoral programs have their advantages and disadvantages. Ultimately, the choice between pursuing a Ph.D versus a Psy.D. typically hinges on how interested students are in working on original research.

Career Options in Research Areas

To give you a fuller understanding of the breadth of psychology as a field of study, we'll briefly examine the nine major research areas in the discipline and some selected career options in these areas. Psychologists in these subfields are most likely to work in academic settings, where they teach undergraduate and/or graduate students and conduct research in their areas of interest. Faculty members who teach undergraduates typically do more teaching and less research than faculty who teach graduate students. Most faculty members in psychology do some re-

search, although expectations for research vary depending on the nature of the college.

Cognitive psychology.   The field of cognitive psychology is concerned with thinking and mental activity—how people (and animals) acquire, process, retrieve, and apply information. Cognitive psychologists also focus on language, problem solving, concept formation, mental imagery, reasoning, decision making, and creativity. Examples of research topics in the field include the effects of encoding strategies on memory retention, the influence of bilingualism on language development, and the factors that people weigh in making risky decisions. Chapters 7 and 8 in this text provide extensive coverage of cognitive psychology topics. Most cognitive psychologists teach and conduct research in academic settings, but they can also use their expertise in business, government, and military settings (which, typically, pay better than academia). For example, some work in computer programming and artificial intelligence. Others may work in management science, applying their knowledge of problem solving and decision making.

Developmental psychology.   Developmental psychologists study how individuals develop physically, intellectually, socially, and emotionally over the lifespan ("from womb to tomb," as some say). Some developmental psychologists focus on just one period of life (for example, childhood or later adulthood), while others study development across the entire lifespan. In a field so broad, the research questions are practically limitless. Examples of research topics include the psychological and social effects of shyness in childhood, conformity to peer pressure in adolescence, and the effects of a spouse's death on the surviving partner. Developmental psychology topics are covered primarily in Chapter 11 of this text, although language development is discussed in Chapter 8, and personality development in Chapter 12. As for career options, developmental psychologists usually teach and conduct research in academic settings. Some serve as consultants to day-care centers, schools, or social service agencies. Others consult with toy and media companies to ensure that toys, games, television programs, and other media products match the cognitive, social, and physical skills of different-aged children.

Experimental psychology.   The term *experimental psychology* refers to a diverse hodgepodge of topics that made up the core of psychology in the first half-century of its existence, including sensation, perception, learning, motivation, and emotion. Re-

searchers in these areas frequently study animals instead of humans. Although psychologists in all research areas conduct experiments, the name for this area reflects its *heavy* reliance on experimentation and its relatively infrequent use of correlational methods. Examples of research topics include how background factors influence object recognition, how variations in reinforcement patterns affect the acquisition of responses, and how external food cues regulate eating behavior. Chapters 4, 6, and 10 in this text provide many examples of research in experimental psychology. The vast majority of experimental psychologists work in academic settings or research laboratories, although their expertise occasionally leads them into applied fields. For example, experts in perception sometimes work in human engineering (see Appendix C).

Physiological psychology.   This domain of research, also known as *biopsychology* and *behavioral neuroscience,* explores how behavior is influenced by genetic, neural, and hormonal functioning. Examples of topics include how the hypothalamus contributes to the regulation of eating behavior, how various drugs produce changes in synaptic transmission, and how the pineal gland regulates biological rhythms. Chapter 3 in the text is devoted exclusively to physiological topics, but biopsychology is so basic it shows up in virtually every chapter of the book, for example in discussions of the biological bases of pain perception (Chapter 4), sleep (5), constraints on learning (6) memory (7), language (8), intelligence (9), emotion (10), aging (11), personality (12), stress responses (13), psychological disorders (14), and drug treatments for mental disorders (15). Most biopsychologists are employed in academia or research centers, but there are applied specialties, such as *clinical neuropsychology,* which you will read about momentarily.

Personality psychology.   This subfield is concerned with understanding and describing people's enduring behavior patterns and the psychological processes that underlie them (personality traits, for example). Personality psychology also focuses on how personality develops and the factors that shape it (heredity and parenting, for example). Some personality psychologists develop psychological tests and other techniques by which to study and evaluate aspects of personality (interests, creativity, and so forth). Examples of research topics include the behavioral correlates of personality traits, such as extraversion or conscientiousness, the impact of self-efficacy on sports performance, and whether culture influences

personality structure. Personality topics are mostly covered in Chapter 12 of this text. Career options for personality psychologists include teaching and conducting research in university settings and working for companies that develop personality tests.

Psychometrics.   This area of research is concerned with the precise measurement of behavior and mental processes. Psychologists in this field design psychological tests to measure various aspects of personality, intelligence, and specific abilities. In their work, psychometricians are concerned about ensuring that psychological tests are reliable, valid, and used fairly, among other things. Psychometrics also includes the development of statistical procedures and computer programs to execute these procedures. Examples of research topics include exploring cultural variations in average scores on tests of mental abilities, analyzing the causes of generational changes in measured intelligence, and investigating the relationship between IQ scores and vocational success. Psychometric topics are examined mainly in Chapter 9 of this text but also are considered in the Chapter 12 application on personality testing. Measurement psychologists typically work in academic settings or for companies that develop psychological tests.

Educational psychology.   Educational psychologists study the intertwined processes of teaching and learning, including a wide range of relevant factors such as motivation, abilities, learning styles, classroom diversity, curriculum design, instructional methods, and achievement testing. Educational psychologists attempt to understand how students learn and then develop materials and strategies to enhance the teaching process. Examples of research topics include comparing strategies and techniques for teaching reading, analyzing the effects of verbal praise on student motivation, and exploring the effects of mainstreaming on children with various types of disabilities. Educational psychology topics mainly appear in Chapter 9 of this text. Most educational psychologists are trained in departments or colleges of education, as opposed to departments of psychology. They are usually employed in academic settings.

Health psychology.   Health psychologists are concerned with the role of psychological factors in the promotion and maintenance of good health, the prevention and treatment of illness, and the formulation of health policy. They study important societal health concerns such as teenage pregnancy, substance abuse, poor nutrition, and sedentary lifestyles. Examples of research topics include how to

enhance the effectiveness of smoking cessation programs, how stress modulates immune system responding, and how to increase adherence to medical advice. Health psychology is covered primarily in Chapter 13 of this text. Health psychologists typically teach and conduct research in universities or medical schools. That said, a fair number of health psychologists are also involved in applied work. They frequently treat patients in hospitals, rehabilitation centers, or other health care settings. For example, they may assist patients with stress management, relaxation training, pain management, or medication compliance. Health psychology may eventually become a distinct applied specialty, but at present most health psychologists in professional practice first obtain degrees in clinical or counseling psychology and then do postdoctoral training in applications of health psychology (Kuther & Morgan, 2007).

Social psychology.   Social psychologists study how other people influence our beliefs, feelings, and behaviors. Some general topics of interest to social psychologists are attitude formation and change, conformity, helping behavior, aggression, prejudice, and interpersonal attraction. Examples of more specific research topics include how physical appearance sways perceptions of personality and competence, how attachment styles influence romantic relationships, how fear appeals work in persuasion, and how culture is related to social loafing. Social psychology is mainly covered in Chapter 16, but the social roots and contexts of behavior surface throughout the book. Examples of social psychology topics in other chapters include the effects of expectations on social perceptions (Chapter 1), the effect of anxiety on the need to be with others (2), the influence of social models on aggressive behavior (6), the sociocultural bases of mating preferences (10), the socialization of gender roles (11), social cognitive approaches to personality (12), the influence of social support on physical health (13), and the relationship between attributional style and depression (14). Most social psychologists work in academic settings, but the applied nature of the subfield also lends itself to work outside academia. For example, some social psychologists consult or work for federal agencies or for businesses that conduct research in marketing and product development.

Career Options in Applied Areas

As noted in Chapter 1, psychology is also made up of various applied subfields. Applied psychology has grown rapidly since World War II sparked a revolution in the training of clinical psychologists. Indeed, today psychologists working in applied fields

outnumber those who focus mainly on research by a sizable margin. We will look at six applied areas of specialization: clinical psychology, counseling psychology, clinical neuropsychology, school psychology, forensic psychology, and industrial/organizational psychology.

Clinical psychology.   Clinical psychologists assess, diagnose, and treat people with psychological problems and disorders. They may act as therapists for people experiencing normal psychological crises (grief, for example) or for individuals suffering from severe, chronic disorders (bipolar disorder and schizophrenia, for example). Some clinical psychologists are generalists who work with a wide variety of populations, while others work with specific groups such as children, the elderly, or those with specific disorders (for example, schizophrenia). They may work with individuals or groups. Clinical psychologists are educated in university-based psychology departments or professional schools of psychology. Clinical psychologists can work in a diverse array of settings: academia, hospitals and medical centers, community mental health centers, or private practice. The nature of their work can also be wide ranging: administering and interpreting psychological tests, providing psychotherapy, teaching, conducting research, consulting, and serving in administrative capacities. Clinical psychology is the largest applied area in the field by far, as about two-thirds of applied psychologists are found in this specialty (see Chapter 1). Issues related to clinical psychology are mostly discussed in Chapters 14 and 15 of this text.

Counseling psychology.   Counseling psychologists do many of the same things that clinical psychologists do. However, counseling psychologists *tend* to focus more on persons with normal adjustment problems rather than on those suffering from severe psychological disorders. Also, the testing they do is usually for career counseling rather than for diagnosing serious psychological disorders. Like clinical psychologists, some counseling psychologists are generalists who work with a wide variety of problems and populations, whereas others specialize in family, marital, or career counseling. Counseling psychology programs are offered in psychology departments, in professional schools of psychology, and in colleges or departments of education. Counseling psychologists are employed in private practice, colleges and universities (in the classroom or in counseling centers), community mental health centers, government agencies, and corporations (providing testing and therapy or serving in administrative roles). Issues related to counseling psychol-

ogy are mostly discussed in Chapters 14 and 15 of this text.

Clinical neuropsychology.   As its name suggests, this relatively new specialization combines clinical psychology (assessment and psychotherapy) and behavioral neuroscience (the study of the neural bases of behavior). Clinical neuropsychologists assess and treat individuals with central nervous system dysfunctions such as traumatic brain injury, stroke, dementia, and seizure disorders. Clinical neuropsychologists must first obtain a doctoral degree in clinical psychology. Because of the specialized nature of their work, they must also complete additional training in clinical neuropsychology during a year-long internship or additional postdoctoral study (Kuther & Morgan, 2007). Clinical neuropsychologists work in a variety of settings, including universities, hospitals, medical centers, and private practice. Topics related to clinical neuropsychology mostly surface in Chapter 3.

School psychology.   School psychologists strive to promote the cognitive, emotional, and social development of children in educational settings. They deal with such issues as study skills, time management, family problems, and alcohol and drug problems. School psychologists use psychological tests to assess students' psychoeducational abilities and to understand the nature of their problems. They also counsel students and their parents and often serve as consultants to parents, teachers, and school administrators. School psychologists are typically trained in departments or colleges of education (versus departments of psychology). Many school psychologists have Ph.D. or Ed.D. degrees; others obtain the Ed.S. (education specialist), a degree between a master's and doctoral degree. Most school psychologists work in public school systems, often traveling among schools. Other employment settings include community mental health centers, criminal justice settings, hospitals, and private practice. Some topics related to school psychology can be found in Chapter 9.

Forensic psychology.   In forensic psychology, psychological principles are applied to the legal system. Thus forensic psychologists are concerned with child custody decisions and involuntary commitment, among other issues. Increasingly, forensic psychologists play a role in personal injury, medical malpractice, and worker's compensation litigation. Forensic psychologists often serve as expert witnesses in criminal trials and may, occasionally, help develop criminal profiles. Most forensic psychologists are trained as clinical or counseling psychologists. Some forensic psychologists have both

doctoral and law degrees. Forensic psychologists may also be involved in developing public policies involving the law and mental health issues. Forensic psychologists work in a variety of settings, including prisons, jails, community mental health centers, and agencies that provide court-related services. Issues related to forensic psychology are discussed briefly in Chapter 14.

Industrial/organizational psychology.   Industrial/organizational (I/O) psychology is concerned with the application of psychological principles in the workplace. I/O psychologists are mainly interested in selecting employees, improving organizational effectiveness and the quality of work life, and designing work environments to match people's capacities and limitations. Most I/O psychologists are employed in business and government settings. Many head up or work in human resources departments, guiding personnel selection, employee training and development, and performance evaluation. I/O psychologists may also recommend organizational structures, policies, and procedures that will enhance organizational effectiveness. Others serve as consultants to business and industry. I/O psychologists who are interested in human factors work to help companies design machines and consumer products that mesh with human information processing capacities and response propensities. Some I/O psychologists teach and conduct research in psychology or business departments. Unlike the other professional areas of psychology, I/O psychology is not a mental health specialty requiring licensure, but it is an important, growing, and widely practiced area of applied psychology. Industrial/organizational psychology is covered in some depth in Appendix C.

Gaining Admission to Graduate School

The most important requirements for admission to graduate school are high scores on the Graduate Record Exam (GRE), excellent grades, glowing faculty recommendations, and research experience. For the record, it is much harder to gain admission to a doctoral program than a master's program. Common *minimum* scores required on the GRE verbal and quantitative sections for doctoral programs are around 550 to 600 (on each test); for master's programs, they hover around 500. The *minimum* cumulative grade-point average for admission to doctoral programs is typically around 3.2; for a master's program, it is around 3.0. On average, admitted students tend to have GPAs that are quite a bit higher

than these minimum figures. Gaining admission to Ph.D. programs in clinical psychology is roughly as competitive and challenging as gaining admission to medical school. Of course, requirements vary among programs within the two levels. Departments with excellent reputations usually have more stringent requirements.

Early Preparation

Early in your college career you may not know whether you will want to try to gain admission to graduate school. To keep this educational door open until you are sure that you want to close it, keep the following points in mind.

1. *Begin early to develop the knowledge and skills graduate programs seek.* As with the job search, you need to begin early to develop the qualities listed in Figure D.2, as they are also important to success in graduate school. In addition, you must hone your verbal, quantitative, and critical thinking skills to a very high degree and be able to demonstrate that you have these skills through your GRE scores, grades, and letters of recommendation. Demonstrating that you have research experience is also important. An excellent way to start is to volunteer to help faculty members with their research. Also note that graduate schools place much less emphasis on extracurricular activities than employers do.

2. *Keep your grades up.* Performing well in all of your classes will help you to learn the information and develop the thinking skills that will permit you to score high on the GRE. It is especially important to do well in your Research Methods and Statistics courses. Good grades will also make you eligible for membership in Psi Chi, the national honor society in psychology.

3. *Position yourself to obtain strong letters of recommendation from three faculty members.* Graduate schools want recommendations only from faculty members. (For employers, recommendations from supervisors and clergy are also acceptable.) Try to take some smaller courses that may enable your professors to get to know you and to become familiar with your work. Otherwise, it will be difficult for them to write good letters of recommendation for you.

Next Steps

You need to prepare your applications for graduate school during the fall term of your senior year. Thus, in your junior year, you should begin identifying the subfield (clinical or social, for instance) in which you want to specialize, as well as schools that interest you. The graduate school application process is complicated and involves dealing with information and issues that are unfamiliar to virtually all students. Thus, it is essential to identify a knowledgeable faculty member in the psychology department at your school to advise you about the admissions process. Although Careers Services' staff members are experts on career issues, they are far less knowledgeable about graduate school admissions. For details about the process of applying to graduate programs in psychology, see Web Link D.1.

Critical Thinking About Internet Research Sources: What Students Need to Know

by Vincent W. Hevern (LeMoyne College)

Is the earth a globe or flat as a pancake? Was Copernicus right that the sun stands at the center of the solar system or does it circle the earth? Did Neil Armstrong really set foot on the lunar surface in 1969 or did NASA stage all those moon landings at a secret movie lot somewhere in the American desert? Probably 99.9999% of people know that the earth is round, Copernicus was right, and Armstrong really walked on the moon. But, type these four words— "flat earth Charles Johnson"—into Google, Yahoo, or another Internet search engine and you'll discover what the other 0.0001% believe. The late Mr. Johnson claimed that he could prove the earth was flat, Copernicus lied, and NASA has tricked us all for decades. So, who's right? After all, information supporting the "Flat Earth" hypothesis can be found on the Internet. Isn't that enough to justify you becoming a "Flat Earther" yourself?

I am starting out with this silly example to highlight a serious problem that students and teachers face in the 21st century: it is easy to find a lot of terrible as well as excellent information online. And, when students (and some teachers, too) don't critically judge their information sources, the overall quality of their research slips (Brown, Freeman, & Williamson, 2000). We live at a time when the amount and availability of information is growing exponentially. But our use of all that data is often handicapped, as it seems harder and harder to figure out where to find, and how to evaluate, research sources. So, whether you are exploring psychology as your major or just because it is an interesting subject, you need to learn how to think critically about Internet-based sources of information in psychology (and every other subject). When you finish school, you may find yourself working in business or for a governmental agency or even in another academic setting. Wherever your future takes you, your skills at finding and evaluating information online will be important and valued. I hope that some of the suggestions in this essay will help you learn to be a better researcher online.

Two Fundamental Facts about Research

No matter how large the Internet grows, libraries will continue to be the foundation for good research.

Yet, as Jenson (2004) argues, "many students are convinced that they can and should do all of their library work in their pajamas and slippers from the relative comfort of their dorm rooms or apartments" (p. 111). If that's your belief, frankly you will not become a better researcher, whether online or off. Colleges continue to spend hundreds of thousands to millions of dollars every year on their libraries because libraries remain the principal repositories of sound, scholarly information. That money also pays for librarians who have special skills and knowledge that permit them to help students and faculty with their research. So, the most basic rule of informational literacy states that *you need to know what is in your school's library.* And, to do so, you should consult the professional reference librarians there to help you. Because the best materials for research in cyberspace are often rooted in print-based library resources, you should learn the basics of the library to enhance your sophistication online.

The second fundamental fact can be summed up by the phrase, "No pain, no gain." It takes time and real effort to develop the skills necessary to be effective in seeking scholarly information. Just as you wouldn't think of playing a varsity sport unless you had trained for it over many months or years, *your ability to conduct research requires regular practice.* In fact, studies usually find that hard work and practice—more so than talent or genius—are what distinguishes experts from other people (van Gelder, 2005). A corollary to the need for practice is the notion that *good research itself takes time.* Very few students can gather the sources needed for an important report in just a few hours or overnight. Assembling the data, weighing the arguments, synthesizing the best materials, and preparing a report in your own words requires dedicated time and attention. That said, the process of research does get easier with experience.

Criteria for Quality on the Net

So, what are the standards or criteria by which you can judge the quality of a webpage or resource? What can you do to increase the chances that the material you take from the Internet is worth your effort? In recent years, information specialists have explored how to answer these questions. Their studies have

come to slightly different conclusions, but there is substantial agreement about what characteristics are associated with quality on the web. The rest of this essay synthesizes their work and my own experience from over a decade of helping students and teachers use the Net (see **Figure E.1** for an overview). If I had to reduce this advice to its simplest terms, the most important key to finding quality resources online will always be the *active exercise of judgment and critical thinking*.

Let's discuss the process of finding sources first. *It is important to understand the difference between online databases and Internet search engines*. Although it is simple and painless to type a phrase into Google or Yahoo! or another Internet search engine, these engines should not normally be the first or only mechanism you use to find resources. It is a better idea to go to the indexes your school's library provides. These indexes can often be accessed through a library's webpage. By subscribing to various online databases (such as PsycINFO and full-text digital journal archives such as PsycARTICLES), your library has already pointed out the most direct path to finding quality materials. If you do use an Internet search engine, try the more specialized ones such as Google Scholar <http://scholar.google.com/> or Scirus <www.scirus.com/>. And remember, it may be prudent to ask your school's reference librarian for suggestions as you develop your own research competence.

It is also critical that you understand the difference between print-based and web-based sources. Online databases such as PsycINFO will give you *abstracts* (brief summaries) of articles from professional journals. The articles themselves may be found in any of three places: in digital archives online, on the shelves of your school's library, or via interlibrary loan from another school. Every school has different levels of access or availability for different journals. Thus, print-based sources, particularly journal articles, may require you to recover them in person rather than online. On the other hand, Internet search engines will generally lead you to sources at different websites. The materials at these sites may appear directly on your web browser, or you may need to download the documents to your personal computer.

Once you have found such sources, how do you evaluate if they are worthwhile? The comments that follow suggest what you should think about.

Identity and Qualifications of the Authors

The Internet is a kind of worldwide democracy. Just about anyone—qualified or not—can construct a webpage and put what they want to say online. With so few restrictions on Internet publishing, the range and quality of online resources is bound to vary from invaluable to completely worthless. So, researchers who turn to the Net need to ask two related questions: *Who has written this material?* and *What are their qualifications for so doing?* These are probably the two most important guides to the quality of online resources.

Sometimes you will find no clues to the identity of the author of a particular webpage or resource—no name, no organizational affiliation, nothing that reveals the authorship of the material. If this is the case, you should be skeptical about relying on this

Figure E.1
Evaluating online resources. The questions listed here, which draw heavily on the work of Alexander and Tate (1999), can help you to evaluate the quality and reliability of resource materials found on the Internet.

Questions to Ask in Evaluating Materials on the Internet

1. **Identity and qualifications of the author(s)**
   - Who is the author of the material? Is the author identified or anonymous?
   - What is the author's academic or professional background and experience?
   - Is the author writing within or outside his/her area of expertise and skill?
   - If the material is the product of a group (a committee, governmental agency, or the like), what is that group's qualifications or expertise regarding this subject?

2. **Publisher or sponsor of the website**
   - Is the material self-published by the author or is there some recognized organization (university, medical center, government agency, nonprofit foundation, and so forth) that sponsors the website for the material?
   - Does the site's sponsor or publisher have a positive reputation?

3. **Balance, objectivity, and independence**
   - Does the material or website strive for balance and objectivity rather than use extreme, inflammatory, or highly subjective language or opinions?
   - Is more than one point of view evident at the site?
   - If the material takes a strong stand on one side of a controversial issue, does the author or site acknowledge there may be another side to the matter?
   - Is the website sponsored by any commercial or political organization that advocates for a particular point of view?
   - Does the author have any financial or commercial interest that might conflict with a fair or objective presentation of the topic?
   - Is the material drawn from a site that sells a product or solicits customers for a service?

4. **Quality of online presentation**
   - Is the site well organized or designed so that browsers can easily visit and retrieve information?
   - Does the site or online material show care in its preparation, such as proper spelling and good grammar in all posted materials?
   - Does the site work effectively, so that the links to subpages and external sites are accurate and helpful?
   - How recently has the site been updated? Does the site show evidence that someone regularly attends to it with corrections, new materials, and so forth?

5. **Other cues to quality**
   - Does the material contain clear and useful references to other scholarship from journals, professional books, and recognized research studies?
   - Have supporting references in the material been published in recent years, or do they include mostly out-of-date, or possibly obsolete sources?
   - Have any editors or external reviewers judged the quality of the material at the site?

information. It's hard to defend the quality of a work when "Anonymous" is the author.

Suppose one or more authors are listed by name. The next task is to discover the *qualifications* of these authors. Do they have some type of expertise to justify writing the online material or constructing the online site? You should look for a statement of an author's academic credentials (such as an advanced degree like a Ph.D. or an M.D.) or appropriate work experience (such as "director of personnel" at a company or "senior researcher" at a laboratory). You may be able to read through a résumé at a personal webpage showing the author's qualifications. You should also try to determine whether the author has published on a similar topic in reputable, peer-reviewed journals or belongs to professional or scholarly organizations concerned with the subject.

There are other cautions to keep in mind. Some authors may be qualified to comment on one topic but go beyond their expertise into other domains of knowledge—for example, a physician commenting on economics or a biologist on educational methods. Researchers need to be cautious with writers who move too far away from their fields of specialization. Another consideration is whether authors may have a financial stake or commercial interest in the issue that might compromise their objectivity.

Finally, suppose the "author" of a web-based publication has an institutional identity such as a professional association, a governmental agency, a research center, or a nonprofit organization. How should qualifications be weighed in such a case? Certainly the overall reputation of the institutional author should be recognized. For example, a consensus statement on a treatment approach produced by the National Institute of Mental Health or a report on the employment characteristics of psychologists issued by the American Psychological Association would both be rated positively as reference sources. You may also check whether a broad corporate board of editors or advisors is associated with an institutional voice on the Net. However, beware of fancy-sounding "Institutes" or "Commissions" or "Associations" that may be the product of a single person or handful of individuals and serve only to artificially embellish the opinions of their creators.

Publisher or Sponsor of the Website

Book authors traditionally use print publishers to promote and distribute their writings. In turn, publishers place their reputations on the line by issuing new books. Discerning readers rely on a publisher's overall standing when they consider whether to acquire new works. Especially in academic publishing, readers know that an editorial and review pro-

cess precedes publication and that such efforts seek to ensure a high level of quality for the published material. Indeed, the essence of academic scholarship lies in a willingness to submit research to pre-publication critiques by knowledgeable colleagues. Occasionally, though, an author circumvents the editorial and peer review process and pays to have his or her book set in print directly. This practice is called "vanity publishing" and is usually looked down upon by other scholars.

In a practice reminiscent of vanity publishing, many web authors post materials online directly through commercial or free Internet service providers. Because these writings have not been edited or evaluated prior to their publication, you need to be cautious in judging their quality. This is not to disparage all self-published resources on the web. Clearly, experts have posted some valuable resources online without peer review. But, in the absence of a clear process of scholarly peer review, you must look for other indicators of quality. For this reason, the overall qualifications of an author as an expert may be crucial in determining whether to use a resource published without peer review.

Websites that are sponsored by academic institutions, government agencies, and nonprofit or scholarly organizations have URLs that end with the designation *.edu, .gov,* or *.org* rather than *.com* or *.net.* Such sites would be expected to offer some assurance of higher quality for data posted there. A particular clue to quality at corporate sites may be a copyright notice by a sponsoring organization rather than a single individual. Often located at the bottom of a webpage, this notice may signal that the organization is willing to put its reputation behind the resource. For example, there are many online health information centers that range in quality from dismal to superb. At one excellent site, The Virtual Hospital <www.uihealthcare.com/vh>, it is significant to find the notice on its title page, "Copyright © 2006 The University of Iowa."

Balance, Objectivity, and Independence

At the checkout line in a supermarket, shoppers often face a set of tabloid newspapers with outrageous headlines and the promise of lurid stories inside. Many people pick up a copy of their favorite tabloid as entertainment, something to be read purely for relaxation and enjoyment but not as an objective or reliable source of reporting about the world. Although tabloid papers are an extreme example, other sources of information should arouse similar suspicions because of their subjective, unbalanced, and biased style of presentation. In similar fashion, Internet resources should be evaluated for

their apparent balance and objectivity. Certainly, the presence of language, graphic images, or opinions that are extreme, inflammatory, or highly subjective suggests that the material should be treated with some skepticism. The more extreme, vulgar, or intemperate the manner of presentation, the less likely that the resource is reliable and trustworthy.

A more difficult case arises from material found on sites clearly advocating a particular point of view, such as those for a lobbying group, political movement, or professional advocacy or commercial trade association. Researchers should expect that resources available at these sites will support the point of view of the group. This fact does not necessarily disqualify the importance of materials found there. The sponsoring organizations may provide valuable information for visitors to their sites. Greater reliance can probably be given to resources found on a site that acknowledges there is more than one side to a controversial issue or, even, that the topic is controversial in the first place. Some sites even offer links to the opposing side of a disputed topic. This openness should inspire confidence by users of the site because it suggests a sense of fairness.

A frequent challenge to researchers of psychological topics arises from commercial sites that stand to make money or gain new customers on the basis of what they post online. These sites may be businesses (with a *.com* address) or may be allied with the professional office or practice of individuals such as psychotherapists or physicians. Sometimes these sites offer a "Resource Center" or similar area that is filled with articles relating to the product or service of the site's sponsor. These articles may include scientific-sounding titles and come from magazines, journals, or books that seem to be similarly professional. Most evaluators warn researchers to be careful when using materials from any site that has a direct financial motivation in sharing information. Finding quality in online materials is always a judgment call, and the more you know about a topic from other sources, the better you can make that call at commercial sites.

Quality of Online Presentation and Other Cues

Another important index of quality is the care with which websites and materials have been organized and maintained. You should consider how easily you can use a website. Do the hypertext links within the site work or do they point to empty or missing pages? Can visitors easily find the information they are looking for? Is there evidence that the design of the site was carefully considered and executed? Similarly, the actual text of materials retrieved from the

Net should be free from gross errors. Poor grammar and improper spelling usually signal that something is amiss. Reputable scholars are fanatical about eliminating sloppiness or careless mistakes in what they write. They believe any such errors would suggest a parallel sloppiness in their thinking. Thus, the presence of mechanical and stylistic mistakes at a website or in a document should raise doubts about how reputable the actual content of a resource may be. Finally, more credibility can be assigned to materials retrieved from sites that are frequently updated and carefully corrected. You should look for clear dates on pages containing important information. Ideally, one date will indicate when the page was first posted online and another when it was last changed or revised.

When I use the Net for research purposes, I use at least two further cues to evaluate the quality of the material or sites I find. First, in articles or papers online, I look at the references used by the author and consider whether they include scholarly materials from journals, professional books, or other recognized research sources. These sources should go well beyond the author's own previous writings. Second, I examine the dates of the supporting references. How recent are they? Do they include sources published in the last several years? Or, do they include only older and possibly out-of-date materials? The more up-to-date the references, the more I tend to trust the source.

A Final Note of Advice

I hope the suggestions summarized here make it clear that any researcher must actively exercise judgment and critical thinking skills in evaluating online resources. Such skills are enormously enhanced when the researcher chooses a balanced overall research strategy. It is one thing to seek a quick fact or a simple definition through a website; it is another to rely on the Internet as the *sole* data source for a major paper or research project. Yet for many people, the Internet is an easily "surfable" medium, one that can quickly lead to information of varying levels of quality. The very ease of conducting research online often seduces student researchers to skip more difficult, but crucially important, steps offline.

The most important strategy a student can bring to any research project is to develop an overall perspective or a broad vantage point regarding the topic of the project. This situation is unlikely to happen unless the investigator uses sources of different types—scholarly books, journal and magazine articles, and printed research reports—*in addition to* ma-

terials retrieved from the Internet. It is both easy to understand, but embarrassing in the long run, when a student hands in a paper with only Internet-based sources and later discovers in a professor's grading that the Net provided a biased or slanted view of the topic. Without the counterbalance of non-Net sources, a student risks seriously misjudging how psychologists, physicians, and other research scientists actually approach an issue. So, my final suggestion about research is a simple rule of thumb: The longer and more important the research project or paper, the broader the kinds of references you should use to answer the research question.

For Further Reference and Reading

Students who wish to further enhance their ability to evaluate Internet materials and sites should consider these outstanding online resources:

GLOSSARY

A

Absolute refractory period The minimum length of time after an action potential during which another action potential cannot begin.

Absolute threshold The minimum amount of stimulation that an organism can detect for a specific type of sensory input.

Achievement motive The need to master difficult challenges, to outperform others, and to meet high standards of excellence.

Achievement tests Tests that gauge a person's mastery and knowledge of various subjects.

Acquired immune deficiency syndrome (AIDS) A disorder in which the immune system is gradually weakened and eventually disabled by the human immunodeficiency virus (HIV).

Acquisition The formation of a new conditioned response tendency.

Action potential A brief change in a neuron's electrical charge.

Acute stressors Threatening events that have a relatively short duration and a clear endpoint.

Adaptation An inherited characteristic that increased in a population (through natural selection) because it helped solve a problem of survival or reproduction during the time it emerged.

Additive color mixing Formation of colors by superimposing lights, putting more light in the mixture than exists in any one light by itself.

Adoption studies Research studies that assess hereditary influence by examining the resemblance between adopted children and both their biological and their adoptive parents.

Affective forecasting A person's efforts to predict his or her emotional reactions to future events.

Afferent nerve fibers Axons that carry information inward to the central nervous system from the periphery of the body.

Afterimage A visual image that persists after a stimulus is removed.

Age of viability The age at which a baby can survive in the event of a premature birth.

Aggression Any behavior that is intended to hurt someone, either physically or verbally.

Agonist A chemical that mimics the action of a neurotransmitter.

Agoraphobia A fear of going out to public places.

Alcohol A variety of beverages containing ethyl alcohol.

Algorithm A methodical, step-by-step procedure for trying all possible alternatives in searching for a solution to a problem.

Amnesia A significant memory loss that is too extensive to be due to normal forgetting. See also *Anterograde amnesia, Retrograde amnesia.*

Androgens The principal class of gonadal hormones in males.

Anecdotal evidence Personal stories about specific incidents and experiences.

Animism The belief that all things are living.

Anorexia nervosa Eating disorder characterized by intense fear of gaining weight, disturbed body image, refusal to maintain normal weight, and dangerous measures to lose weight.

Antagonist A chemical that opposes the action of a neurotransmitter.

Anterograde amnesia Loss of memories for events that occur after a head injury.

Antianxiety drugs Medications that relieve tension, apprehension, and nervousness.

Antidepressant drugs Medications that gradually elevate mood and help bring people out of a depression.

Antipsychotic drugs Medications used to gradually reduce psychotic symptoms, including hyperactivity, mental confusion, hallucinations, and delusions.

Antisocial personality disorder A type of personality disorder marked by impulsive, callous, manipulative, aggressive, and irresponsible behavior that reflects a failure to accept social norms.

Anxiety disorders A class of disorders marked by feelings of excessive apprehension and anxiety.

Applied psychology The branch of psychology concerned with everyday, practical problems.

Approach-approach conflict A conflict situation in which a choice must be made between two attractive goals.

Approach-avoidance conflict A conflict situation in which a choice must be made about whether to pursue a single goal that has both attractive and unattractive aspects.

Aptitude tests Psychological tests used to assess talent for specific types of mental ability.

Archetypes According to Jung, emotionally charged images and thought forms that have universal meaning.

Argument One or more premises used to provide support for a conclusion.

Ascending reticular activating system (ARAS) The afferent fibers running through the reticular formation that influence physiological arousal.

Assumptions Premises for which no proof or evidence is offered.

Attachment A close, emotional bond of affection between infants and their caregivers.

Attention Focusing awareness on a narrowed range of stimuli or events.

Attitudes Orientations that locate objects of thought on dimensions of judgment.

Attributions Inferences that people draw about the causes of events, others' behavior, and their own behavior.

Auditory localization Locating the source of a sound in space.

Autonomic nervous system (ANS) The system of nerves that connect to the heart, blood vessels, smooth muscles, and glands.

Availability heuristic Basing the estimated probability of an event on the ease with which relevant instances come to mind.

Aversion therapy A behavior therapy in which an aversive stimulus is paired with a stimulus that elicits an undesirable response.

Avoidance-avoidance conflict A conflict situation in which a choice must be made between two unattractive goals.

Avoidance learning Learning that has occurred when an organism engages in a response that prevents aversive stimulation from occurring.

Axon A long, thin fiber that transmits signals away from the neuron cell body to other neurons, or to muscles or glands.

B

Basilar membrane A structure that runs the length of the cochlea in the inner ear and holds the auditory receptors, called hair cells.

Behavior Any overt (observable) response or activity by an organism.

Behavior modification A systematic approach to changing behavior through the application of the principles of conditioning.

Behavior therapies Application of the principles of learning to direct efforts to change clients' maladaptive behaviors.

Behavioral contract A written agreement outlining a promise to adhere to the contingencies of a behavior modification program.

Behaviorism A theoretical orientation based on the premise that scientific psychology should study only observable behavior.

Bilingualism The acquisition of two languages that use different speech sounds, vocabularies, and grammatical rules.

Binge-eating disorder Distress-induced eating binges that are not accompanied by the purging, fasting, and excessive exercise seen in bulimia.

Binocular depth cues Clues about distance based on the differing views of the two eyes.

Biological rhythms Periodic fluctuations in physiological functioning.

Biomedical therapies Physiological interventions intended to reduce symptoms associated with psychological disorders.

Biopsychosocial model A model of illness that holds that physical illness is caused by a complex interaction of biological, psychological, and sociocultural factors.

Bipolar disorder (formerly known as manic-depressive disorder) Mood disorder marked by the experience of both depressed and manic periods.

Bisexuals Persons who seek emotional-sexual relationships with members of either sex.

Body mass index (BMI) Weight (in kilograms) divided by height (in meters) squared (kg/m^2).

Bottom-up processing In form perception, progression from individual elements to the whole.

Bulimia nervosa Eating disorder characterized by habitually engaging in out-of-control overeating followed by unhealthy compensatory efforts, such as self-induced vomiting, fasting, abuse of laxatives and diuretics, and excessive exercise.

Burnout Physical, mental, and emotional exhaustion that is attributable to work-related stress.

Bystander effect A paradoxical social phenomenon in which people are less likely to provide needed help when they are in groups than when they are alone.

C

Cannabis The hemp plant from which marijuana, hashish, and THC are derived.

Case study An in-depth investigation of an individual subject.

Catastrophic thinking Unrealistically pessimistic appraisals of stress that exaggerate the magnitude of one's problems.

Catatonic schizophrenia A type of schizophrenia marked by striking motor disturbances, ranging from muscular rigidity to random motor activity.

Catharsis The release of emotional tension.

Central nervous system (CNS) The brain and the spinal cord.

Centration The tendency to focus on just one feature of a problem, neglecting other important aspects.

Cephalocaudal trend The head-to-foot direction of motor development.

Cerebral cortex The convoluted outer layer of the cerebrum.

Cerebral hemispheres The right and left halves of the cerebrum.

Cerebrospinal fluid (CSF) A solution that fills the hollow cavities (ventricles) of the brain and circulates around the brain and spinal cord.

Channel The medium through which a message is sent.

Chromosomes Threadlike strands of DNA (deoxyribonucleic acid) molecules that carry genetic information.

Chronic stressors Threatening events that have a relatively long duration and no readily apparent time limit.

Chunk A group of familiar stimuli stored as a single unit.

Circadian rhythms The 24-hour biological cycles found in humans and many other species.

Classical conditioning A type of learning in which a neutral stimulus acquires the ability to evoke a response that was originally evoked by another stimulus.

Client-centered therapy An insight therapy that emphasizes providing a supportive emotional climate for clients, who play a major role in determining the pace and direction of their therapy.

Clinical psychologists Psychologists who specialize in the diagnosis and treatment of psychological disorders and everyday behavioral problems.

Clinical psychology The branch of psychology concerned with the diagnosis and treatment of psychological problems and disorders.

Cochlea The fluid-filled, coiled tunnel in the inner ear that contains the receptors for hearing.

Coefficient of determination The percentage of variation in one variable that can be predicted based on the other variable.

Cognition The mental processes involved in acquiring knowledge.

Cognitive-behavioral treatments A varied combination of verbal interventions and behavioral modification techniques used to help clients change maladaptive patterns of thinking.

Cognitive development Transitions in youngsters' patterns of thinking, including reasoning, remembering, and problem solving.

Cognitive dissonance A psychological state that exists when related cognitions are inconsistent.

Cognitive therapy An insight therapy that emphasizes recognizing and changing negative thoughts and maladaptive beliefs.

Cohort effects Differences between age groups that are attributable to the groups growing up in different time periods.

Collective unconscious According to Jung, a storehouse of latent memory traces inherited from people's ancestral past.

Collectivism Putting group goals ahead of personal goals and defining one's identity in terms of the groups one belongs to.

Color blindness Deficiency in the ability to distinguish among colors.

Commitment An intent to maintain a relationship in spite of the difficulties and costs that may arise.

Comorbidity The coexistence of two or more disorders.

Companionate love Warm, trusting, tolerant affection for another whose life is deeply intertwined with one's own.

Compensation According to Adler, efforts to overcome imagined or real inferiorities by developing one's abilities.

Complementary colors Pairs of colors that produce gray tones when added together.

Conceptual hierarchy A multilevel classification system based on common properties among items.

Concordance rate The percentage of twin pairs or other pairs of relatives that exhibit the same disorder.

Conditioned reinforcers. See *Secondary reinforcers*.

Conditioned response (CR) A learned reaction to a conditioned stimulus that occurs because of previous conditioning.

Conditioned stimulus (CS) A previously neutral stimulus that has, through conditioning, acquired the capacity to evoke a conditioned response.

Cones Specialized visual receptors that play a key role in daylight vision and color vision.

Confirmation bias The tendency to seek information that supports one's decisions and beliefs while ignoring disconfirming information.

Conflict A state that occurs when two or more incompatible motivations or behavioral impulses compete for expression.

Conformity The tendency for people to yield to real or imagined social pressure.

Confounding of variables A condition that exists whenever two variables are linked together in a way that makes it difficult to sort out their independent effects.

Conjunction fallacy An error that occurs when people estimate that the odds of two uncertain events happening together are greater than the odds of either event happening alone.

Connectionist models. See *parallel distributed processing (PDP) models*.

Conscious Whatever one is aware of at a particular point in time.

Conservation Piaget's term for the awareness that physical quantities remain constant in spite of changes in their shape or appearance.

Consolidation A hypothetical process involving the gradual conversion of information into durable memory codes stored in long-term memory.

Construct validity The extent to which there is evidence that a test measures a particular hypothetical construct.

Constructive coping Relatively healthful efforts that people make to deal with stressful events.

Content validity The degree to which the content of a test is representative of the domain it's supposed to cover.

Continuous reinforcement Reinforcing every instance of a designated response.

Control group Subjects in a study who do not receive the special treatment given to the experimental group.

Convergence A cue to depth that involves sensing the eyes converging toward each other as they focus on closer objects.

Convergent thinking Narrowing down a list of alternatives to converge on a single correct answer.

Conversion disorder A somatoform disorder characterized by a significant loss of physical function (with no apparent organic basis), usually in a single organ system.

Coping Active efforts to master, reduce, or tolerate the demands created by stress.

Corpus callosum The structure that connects the two cerebral hemispheres.

Correlation The extent to which two variables are related to each other.

Correlation coefficient A numerical index of the degree of relationship between two variables.

Counseling psychologists Psychologists who specialize in the treatment of everyday adjustment problems.

Creativity The generation of ideas that are original, novel, and useful.

Criterion-related validity Test validity that is estimated by correlating subjects' scores on a test with their scores on an independent criterion (another measure) of the trait assessed by the test.

Critical period A limited time span in the development of an organism when it is optimal for certain capacities to emerge because the organism is especially responsive to certain experiences.

Critical thinking The use of cognitive skills and strategies that increase the probability of a desired outcome.

Cross-sectional design A research design in which investigators compare groups of subjects of differing age who are observed at a single point in time.

Culture The widely shared customs, beliefs, values, norms, institutions, and other products of a community that are transmitted socially across generations.

Crystallized intelligence The ability to apply acquired knowledge and skills in problem solving.

Culture-bound disorders Abnormal syndromes found only in a few cultural groups.

Cumulative recorder A graphic record of reinforcement and responding in a Skinner box as a function of time.

Cyclothymic disorder Exhibiting chronic but relatively mild symptoms of bipolar disturbance.

D

Dark adaptation The process in which the eyes become more sensitive to light in low illumination.

Data collection techniques Procedures for making empirical observations and measurements.

Decay theory The idea that forgetting occurs because memory traces fade with time.

Decision making The process of evaluating alternatives and making choices among them.

Declarative memory system Memory for factual information.

Deep brain stimulation (DBS) A treatment approach that involves a thin electrode being surgically implanted in the brain and connected to an implanted pulse generator so that various electrical currents can be delivered to brain tissue adjacent to the electrode.

Defense mechanisms Largely unconscious reactions that protect a person from unpleasant emotions such as anxiety and guilt.

Defensive attribution The tendency to blame victims for their misfortune, so that one feels less likely to be victimized in a similar way.

Deinstitutionalization Transferring the treatment of mental illness from inpatient institutions to community-based facilities that emphasize outpatient care.

Delusions False beliefs that are maintained even though they are clearly out of touch with reality.

Dementia An abnormal condition marked by multiple cognitive defects that include memory impairment.

Dendrites Branchlike parts of a neuron that are specialized to receive information.

Dependent variable In an experiment, the variable that is thought to be affected by the manipulation of the independent variable.

Depth perception Interpretation of visual cues that indicate how near or far away objects are.

Descriptive statistics Statistics that are used to organize and summarize data.

Development The sequence of age-related changes that occur as a person progresses from conception to death.

Developmental norms The average age at which individuals display various behaviors and abilities.

Deviation IQ scores Scores that locate subjects precisely within the normal distribution, using the standard deviation as the unit of measurement.

Diagnosis Distinguishing one illness from another.

Discrimination Behaving differently, usually unfairly, toward the members of a group.

Discriminative stimuli Cues that influence operant behavior by indicating the probable consequences (reinforcement or nonreinforcement) of a response.

Disorganized schizophrenia A type of schizophrenia in which particularly severe deterioration of adaptive behavior is seen.

Displacement Diverting emotional feelings (usually anger) from their original source to a substitute target.

Display rules Cultural norms that regulate the appropriate expressions of emotions.

Dissociation A splitting off of mental processes into two separate, simultaneous streams of awareness.

Dissociative amnesia A sudden loss of memory for important personal information that is too extensive to be due to normal forgetting.

Dissociative disorders A class of disorders in which people lose contact with portions of their consciousness or memory, resulting in disruptions in their sense of identity.

Dissociative fugue A disorder in which people lose their memory for their entire lives along with their sense of personal identity.

Dissociative identity disorder (DID) A type of dissociative disorder characterized by the coexistence in one person of two or more largely complete, and usually very different, personalities. Also called multiple-personality disorder.

Distal stimuli Stimuli that lie in the distance (that is, in the world outside the body).

Divergent thinking Trying to expand the range of alternatives by generating many possible solutions.

Dominant gene A gene that is expressed when paired genes are heterozygous (different).

Double-blind procedure A research strategy in which neither subjects nor experimenters know which subjects are in the experimental or control groups.

Dream analysis A psychoanalytic technique in which the therapist interprets the symbolic meaning of the client's dreams.

Drive An internal state of tension that motivates an organism to engage in activities that should reduce the tension.

Dual-coding theory Paivio's theory that memory is enhanced by forming semantic and visual codes, since either can lead to recall.

Dysthymic disorder A chronic depression that is insufficient in severity to merit diagnosis of a major depressive episode.

E

Eating disorders Severe disturbances in eating behavior characterized by preoccupation with weight concerns and unhealthy efforts to control weight.

Eclecticism In psychotherapy, drawing ideas from two or more systems of therapy instead of committing to just one system.

Efferent nerve fibers Axons that carry information outward from the central nervous system to the periphery of the body.

Ego According to Freud, the decision-making component of personality that operates according to the reality principle.

Egocentrism A limited ability to share another person's viewpoint.

Elaboration Linking a stimulus to other information at the time of encoding.

Electrical stimulation of the brain (ESB) Sending a weak electric current into a brain structure to stimulate (activate) it.

Electroconvulsive therapy (ECT) A biomedical treatment in which electric shock is used to produce a cortical seizure accompanied by convulsions.

Electroencephalograph (EEG) A device that monitors the electrical activity of the brain over time by means of recording electrodes attached to the surface of the scalp.

Electromyograph (EMG) A device that records muscular activity and tension.

Electrooculograph (EOG) A device that records eye movements.

Elicit To draw out or bring forth.

Embryonic stage The second stage of prenatal development, lasting from two weeks until the end of the second month.

Emit To send forth.

Emotion A subjective conscious experience (the cognitive component) accompanied by bodily arousal (the physiological component) and by characteristic overt expressions (the behavioral component).

Emotional intelligence (EI) The ability to perceive and express emotion, assimilate emotion in thought, understand and reason with emotion, and regulate emotion.

Empiricism The premise that knowledge should be acquired through observation.

Encoding Forming a memory code.

Encoding specificity principle The idea that the value of a retrieval cue depends on how well it corresponds to the memory code.

Endocrine system A group of glands that secrete chemicals into the bloodstream that help control bodily functioning.

Endorphins The entire family of internally produced chemicals that resemble opiates in structure and effects.

Epidemiology The study of the distribution of mental or physical disorders in a population.

Episodic memory system Chronological, or temporally dated, recollections of personal experiences.

Escape learning A type of learning in which an organism acquires a response that decreases or ends some aversive stimulation.

Estrogens The principal class of gonadal hormones in females.

Ethnocentrism The tendency to view one's own group as superior to others and as the standard for judging the worth of foreign ways.

Etiology The apparent causation and developmental history of an illness.

Evaluative conditioning Efforts to transfer the emotion attached to a UCS to a new CS.

Evolutionary psychology Theoretical perspective that examines behavioral processes in terms of their adaptive value for a species over the course of many generations.

Experiment A research method in which the investigator manipulates a variable under carefully controlled conditions and observes whether any changes occur in a second variable as a result.

Experimental group The subjects in a study who receive some special treatment in regard to the independent variable.

Experimenter bias A phenomenon that occurs when a researcher's expectations or preferences about the outcome of a study influence the results obtained.

Expressed emotion (EE) The degree to which a relative of a patient displays highly critical or emotionally overinvolved attitudes toward the patient.

External attributions Ascribing the causes of behavior to situational demands and environmental constraints.

Extinction The gradual weakening and disappearance of a conditioned response tendency.

Extraneous variables Any variables other than the independent variable that seem likely to influence the dependent variable in a specific study.

F

Factor analysis Statistical analysis of correlations among many variables to identify closely related clusters of variables.

Family studies Scientific studies in which researchers assess hereditary influence by examining blood relatives to see how much they resemble each other on a specific trait.

Farsightedness A vision deficiency in which distant objects are seen clearly but close objects appear blurry.

Fast mapping The process by which children map a word onto an underlying concept after only one exposure to the word.

Feature analysis The process of detecting specific elements in visual input and assembling them into a more complex form.

Feature detectors Neurons that respond selectively to very specific features of more complex stimuli.

Fetal alcohol syndrome A collection of congenital (inborn) problems associated with excessive alcohol use during pregnancy.

Fetal stage The third stage of prenatal development, lasting from two months through birth.

Fight-or-flight response A physiological reaction to threat in which the autonomic nervous system mobilizes the organism for attacking (fight) or fleeing (flight) an enemy.

Fitness The reproductive success (number of descendants) of an individual organism relative to the average reproductive success of the population.

Fixation According to Freud, failure to move forward from one psychosexual stage to another as expected.

Fixed-interval (FI) schedule A reinforcement schedule in which the reinforcer is given for the first response that occurs after a fixed time interval has elapsed.

Fixed-ratio (FR) schedule A reinforcement schedule in which the reinforcer is given after a fixed number of nonreinforced responses.

Flashbulb memories Unusually vivid and detailed recollections of momentous events.

Fluid intelligence Basic reasoning ability, memory capacity, and speed of information processing.

Foot-in-the-door technique Getting people to agree to a small request to increase the chances that they will agree to a larger request later.

Forebrain The largest and most complicated region of the brain, encompassing a variety of structures, including the thalamus, hypothalamus, limbic system, and cerebrum.

Forgetting curve A graph showing retention and forgetting over time.

Fovea A tiny spot in the center of the retina that contains only cones; visual acuity is greatest at this spot.

Framing How issues are posed or how choices are structured.

Fraternal twins Twins that result when two eggs are fertilized simultaneously by different sperm cells, forming two separate zygotes. Also called *dizygotic twins*.

Free association A psychoanalytic technique in which clients spontaneously express their thoughts and feelings exactly as they occur, with as little censorship as possible.

Frequency distribution An orderly arrangement of scores indicating the frequency of each score or group of scores.

Frequency polygon A line figure used to present data from a frequency distribution.

Frequency theory The theory that perception of pitch corresponds to the rate, or frequency, at which the entire basilar membrane vibrates.

Frustration The feeling that people experience in any situation in which their pursuit of some goal is thwarted.

Functional fixedness The tendency to perceive an item only in terms of its most common use.

Functionalism A school of psychology based on the belief that psychology should investigate the function or purpose of consciousness, rather than its structure.

Fundamental attribution error Observers' bias in favor of internal attributions in explaining others' behavior.

G

Galvanic skin response (GSR) An increase in the electrical conductivity of the skin that occurs when sweat glands increase their activity.

Gambler's fallacy The belief that the odds of a chance event increase if the event hasn't occurred recently.

Gate-control theory The idea that incoming pain sensations must pass through a "gate" in the spinal cord that can be closed, thus blocking pain signals.

Gender Culturally constructed distinctions between masculinity and femininity.

Gender differences Actual disparities between the sexes in typical behavior or average ability.

Gender roles Expectations about what is appropriate behavior for each sex.

Gender stereotypes Widely held beliefs about males' and females' abilities, personality traits, and behavior.

General adaptation syndrome Selye's model of the body's stress response, consisting of three stages: alarm, resistance, and exhaustion.

Generalized anxiety disorder A psychological disorder marked by a chronic, high level of anxiety that is not tied to any specific threat.

Genes DNA segments that serve as the key functional units in hereditary transmission.

Genetic mapping The process of determining the location and chemical sequence of specific genes on specific chromosomes.

Genotype A person's genetic makeup.

Germinal stage The first phase of prenatal development, encompassing the first two weeks after conception.

Glia Cells found throughout the nervous system that provide various types of support for neurons.

Glucose A simple sugar that is an important source of energy.

Glucostats Neurons sensitive to glucose in the surrounding fluid.

Group Two or more individuals who interact and are interdependent.

Group cohesiveness The strength of the liking relationships linking group members to each other and to the group itself.

Group polarization A phenomenon that occurs when group discussion strengthens a group's dominant point of view and produces a shift toward a more extreme decision in that direction.

Group therapy The simultaneous treatment of several clients in a group.

Groupthink A process in which members of a cohesive group emphasize concurrence at the expense of critical thinking in arriving at a decision.

Gustatory system The sensory system for taste.

H

Hallucinations Sensory perceptions that occur in the absence of a real, external stimulus, or gross distortions of perceptual input.

Hallucinogens A diverse group of drugs that have powerful effects on mental and emotional functioning, marked most prominently by distortions in sensory and perceptual experience.

Health psychology The subfield of psychology concerned with how psychosocial factors relate to the promotion and maintenance of health and with the causation, prevention, and treatment of illness.

Hedonic adaptation An effect that occurs when the mental scale that people use to judge the pleasantness-unpleasantness of their experiences shifts so that their neutral point, or baseline for comparison, changes.

Heritability ratio An estimate of the proportion of trait variability in a population that is determined by variations in genetic inheritance.

Heterosexuals Persons who seek emotional-sexual relationships with members of the other sex.

Heterozygous condition The situation that occurs when two genes in a specific pair are different.

Heuristic A strategy, guiding principle, or rule of thumb used in solving problems or making decisions.

Hierarchy of needs Maslow's systematic arrangement of needs according to priority, which assumes that basic needs must be met before less basic needs are aroused.

Higher-order conditioning A type of conditioning in which a conditioned stimulus functions as if it were an unconditioned stimulus.

Hill-climbing heuristic Problem-solving approach that entails selecting the alternative at each choice point that appears to lead most directly to one's goal.

Hindbrain The part of the brain that includes the cerebellum and two structures found in the lower part of the brainstem: the medulla and the pons.

Hindsight bias The tendency to mold one's interpretation of the past to fit how events actually turned out.

Histogram A bar graph that presents data from a frequency distribution.

Homeostatsis A state of physiological equilibrium or stability.

Homosexuals Persons who seek emotional-sexual relationships with members of the same sex.

Homozygous condition The situation that occurs when two genes in a specific pair are the same.

Hormones The chemical substances released by the endocrine glands.

Human factors (human engineering) psychology Area of psychology that examines the ways in which work, work systems, and system features can be designed or changed to most effectively correspond with the capabilities and limitations of human beings, often with a focus on the human body.

Humanism A theoretical orientation that emphasizes the unique qualities of humans, especially their freedom and their potential for personal growth.

Hypnosis A systematic procedure that typically produces a heightened state of suggestibility.

Hypochondriasis A somatoform disorder characterized by excessive preoccupation with health concerns and incessant worry about developing physical illnesses.

Hypothalamus A structure found near the base of the forebrain that is involved in the regulation of basic biological needs.

Hypothesis A tentative statement about the relationship between two or more variables.

I

Id According to Freud, the primitive, instinctive component of personality that operates according to the pleasure principle.

Identical twins Twins that emerge from one zygote that splits for unknown reasons. Also called *monozygotic twins.*

Identification Bolstering self-esteem by forming an imaginary or real alliance with some person or group.

Illusory correlation A misperception that occurs when people estimate that they have encountered more confirmations of an association between social traits than they have actually seen.

Immune response The body's defensive reaction to invasion by bacteria, viral agents, or other foreign substances.

Impossible figures Objects that can be represented in two-dimensional pictures but cannot exist in three-dimensional space.

Inattentional blindness Failure to see visible objects or events because one's attention is focused elsewhere.

Incentive An external goal that has the capacity to motivate behaivor.

Inclusive fitness The sum of an individual's own reproductive success plus the effects the organism has on the reproductive success of related others.

Incongruence The degree of disparity between one's self-concept and one's actual experience.

Independent variable In an experiment, a condition or event that an experimenter varies in order to see its impact on another variable.

Individualism Putting personal goals ahead of group goals and defining one's identity in terms of personal attributes rather than group memberships.

Industrial and organizational (I/O) psychology The branch of psychology concerned with human behavior in the work environment.

Industrial psychology Subfield of I/O psychology that deals with the how-to side, including how to select individuals for the right positions, how to evaluate their job performance, how to train them, and how to compensate them.

Inferential statistics Statistics that are used to interpret data and draw conclusions.

Ingroup The group that people belong to and identify with.

Insanity A legal status indicating that a person cannot be held responsible for his or her actions because of mental illness.

Insight In problem solving, the sudden discovery of the correct solution following incorrect attempts based primarily on trial and error.

Insight therapies Psychotherapy methods characterized by verbal interactions intended to enhance clients' self-knowledge and thus promote healthful changes in personality and behavior.

Insomnia Chronic problems in getting adequate sleep.

Instinctive drift The tendency for an animal's innate responses to interfere with conditioning processes.

Integrity tests Standardized measures used to assess attitudes and experience related to honesty and trustworthiness.

Intellectual disability Subnormal general mental ability accompanied by deficiencies in everyday living skills originating prior to age 18.

Intelligence quotient (IQ) A child's mental age divided by chronological age, multiplied by 100.

Intelligence tests Psychological tests that measure general mental ability.

Interference theory The idea that people forget information because of competition from other material.

Intermittent reinforcement A reinforcement schedule in which a designated response is reinforced only some of the time.

Internal attributions Ascribing the causes of behavior to personal dispositions, traits, abilities, and feelings.

Internet addiction Spending an inordinate amount of time on the Internet and being unable to control online use.

Internet-mediated research Studies in which data collection occurs over the web.

Interpersonal attraction Positive feelings toward another.

Interpretation In psychoanalysis, the therapist's attempts to explain the inner significance of the client's thoughts, feelings, memories, and behaviors.

Intimacy Warmth, closeness, and sharing in a relationship.

Introspection Careful, systematic observation of one's own conscious experience.

Involuntary commitment A civil proceeding in which people are hospitalized in psychiatric facilities against their will.

Irreversibility The inability to envision reversing an action.

J

Job satisfaction The positive or negative emotions associated with a job.

Journal A periodical that publishes technical and scholarly material, usually in a narrowly defined area of inquiry.

Just noticeable difference (JND) The smallest difference in the amount of stimulation that a specific sense can detect.

L

Language A set of symbols that convey meaning, and rules for combining those symbols, that can be used to generate an infinite variety of messages.

Language acquisition device (LAD) An innate mechanism or process that facilitates the learning of language.

Latent content According to Freud, the hidden or disguised meaning of the events in a dream.

Latent learning Learning that is not apparent from behavior when it first occurs.

Lateral antagonism A process in the retina that occurs when neural activity in a cell opposes activity in surrounding cells.

Law of effect The principle that if a response in the presence of a stimulus leads to satisfying effects, the association between the stimulus and the response is strengthened.

Leadership The ability to influence and motivate people to pursue organizational goals.

Learned helplessness Passive behavior produced by exposure to unavoidable aversive events.

Learning A relatively durable change in behavior or knowledge that is due to experience.

Lens The transparent eye structure that focuses the light rays falling on the retina.

Lesioning Destroying a piece of the brain.

Levels-of-processing theory The theory holding that deeper levels of mental processing result in longer-lasting memory codes.

Lie detector. See *Polygraph.*

Life changes Any noticeable alterations in one's living circumstances that require readjustment.

Light adaptation The process whereby the eyes become less sensitive to light in high illumination.

Limbic system A densely connected network of structures roughly located along the border between the cerebral cortex and deeper subcortical areas.

Linguistic relativity The theory that one's language determines the nature of one's thought.

Link method Forming a mental image of items to be remembered in a way that links them together.

Long-term memory (LTM) An unlimited capacity store that can hold information over lengthy periods of time.

Long-term potentiation (LTP) A long-lasting increase in neural excitability in synapses along a specific neural pathway.

Longitudinal design A research design in which investigators observe one group of subjects repeatedly over a period of time.

Lowball technique Getting someone to commit to an attractive proposition before revealing the hidden costs.

Lucid dreams Dreams in which people can think clearly about the circumstances of waking life and the fact that they are dreaming, yet they remain asleep in the midst of a vivid dream.

M

Major depressive disorder Mood disorder characterized by persistent feelings of sadness and despair and a loss of interest in previous sources of pleasure.

Manic-depressive disorder See *Bipolar disorder.*

Manifest content According to Freud, the plot of a dream at a surface level.

Matching hypothesis The idea that males and females of approximately equal physical attractiveness are likely to select each other as partners.

Maturation Development that reflects the gradual unfolding of one's genetic blueprint.

MDMA A compound drug related to both amphetamines and hallucinogens, especially mescaline; commonly called "ecstasy."

Mean The arithmetic average of the scores in a distribution.

Mean length of utterance (MLU) The average length of children's spoken statements (measured in phonemes).

Median The score that falls exactly in the center of a distribution of scores.

Medical model The view that it is useful to think of abnormal behavior as a disease.

Meditation A family of mental exercises in which a conscious attempt is made to focus attention in a nonanalytical way.

Menarche The first occurrence of menstruation.

Mental age In intelligence testing, a score that indicates that a child displays the mental ability typical of a child of that chronological (actual) age.

Mental hospital A medical institution specializing in providing inpatient care for psychological disorders.

Mental retardation See *Intellectual disability*.

Mental set Persisting in using problem-solving strategies that have worked in the past.

Mentoring A form of on-the-job training in which a current and often long-term employee (the mentor) is paired with a new employee to aid his or her growth and development within the organization.

Message The information transmitted by a source.

Metalinguistic awareness The ability to reflect on the use of language.

Method of loci A mnemonic device that involves taking an imaginary walk along a familiar path where images of items to be remembered are associated with certain locations.

Midbrain The segment of the brain stem that lies between the hindbrain and the forebrain.

Mirror neurons Neurons that are activated by performing an action or by seeing another monkey or person perform the same action.

Misinformation effect Phenomenon that occurs when participants' recall of an event they witnessed is altered by introducing misleading postevent information.

Mnemonic devices Strategies for enhancing memory.

Mode The score that occurs most frequently in a distribution.

Model A person whose behavior is observed by another.

Monocular depth cues Clues about distance based on the image from either eye alone.

Mood disorders A class of disorders marked by emotional disturbances of varied kinds that may spill over to disrupt physical, perceptual, social, and thought processes.

Mood stabilizers Drugs used to control mood swings in patients with bipolar mood disorders.

Morphemes The smallest units of meaning in a language.

Motion parallax Cue to depth that involves images of objects at different distances moving across the retina at different rates.

Motivated forgetting Purposeful suppression of memories.

Motivation Goal-directed behavior.

Motor development The progression of muscular coordination required for physical activities.

Multiple-personality disorder See *Dissociative identity disorder*.

N

Narcolepsy A disease marked by sudden and irresistible onsets of sleep during normal waking periods.

Narcotics Drugs derived from opium that are capable of relieving pain.

Natural selection Principle stating that heritable characteristics that provide a survival reproductive advantage are more likely than alternative characteristics to be passed on to subsequent generations and thus come to be "selected" over time.

Naturalistic observation A descriptive research method in which the researcher engages in careful, usually prolonged, observation of behavior without intervening directly with the subjects.

Nearsightedness A vision deficiency in which close objects are seen clearly but distant objects appear blurry.

Need for self-actualization The need to fulfill one's potential.

Negative reinforcement The strengthening of a response because it is followed by the removal of an aversive (unpleasant) stimulus.

Negative symptoms Schizophrenic symptoms that involve behavioral deficits, such as flattened emotions, social withdrawal, apathy, impaired attention, and poverty of speech.

Negatively skewed distribution A distribution in which most scores pile up at the high end of the scale.

Nerves Bundles of neuron fibers (axons) that are routed together in the peripheral nervous system.

Neurogenesis The formation of new neurons in the brain.

Neurons Individual cells in the nervous system that receive, integrate, and transmit information.

Neurotransmitters Chemicals that transmit information from one neuron to another.

Night terrors Abrupt awakenings from NREM sleep accompanied by intense autonomic arousal and feelings of panic.

Nightmares Anxiety-arousing dreams that lead to awakening, usually from REM sleep.

Non-REM (NREM) sleep Sleep stages 1 through 4, which are marked by an absence of rapid eye movements, relatively little dreaming, and varied EEG activity.

Nondeclarative memory system Memory for actions, skills, and operations.

Nonsense syllables Consonant-vowel-consonant arrangements that do not correspond to words.

Normal distribution A symmetric, bell-shaped curve that represents the pattern in which many characteristics are dispersed in the population.

Null hypothesis In inferential statistics, the assumption that there is no true relationship between the variables being observed.

O

Obedience A form of compliance that occurs when people follow direct commands, usually from someone in a position of authority.

Obesity The condition of being overweight.

Object permanence Recognizing that objects continue to exist even when they are no longer visible.

Observational learning A type of learning that occurs when an organism's responding is influenced by the observation of others, who are called models.

Obsessive-compulsive disorder (OCD) A type of anxiety disorder marked by persistent, uncontrollable intrusions of unwanted thoughts (obsessions) and urges to engage in senseless rituals (compulsions).

Oedipal complex According to Freud, children's manifestation of erotically tinged desires for their opposite-sex parent, accompanied by feelings of hostility toward their same-sex parent.

Olfactory system The sensory system for smell.

Operant chamber. See *Skinner box*.

Operant conditioning A form of learning in which voluntary responses come to be controlled by their consequences.

Operational definition A definition that describes the actions or operations that will be made to measure or control a variable.

Opiates. See *Narcotics*.

Opponent process theory The theory that color perception depends on receptors that make antagonistic responses to three pairs of colors.

Optic chiasm The point at which the optic nerves from the inside half of each eye cross over and then project to the opposite half of the brain.

Optic disk A hole in the retina where the optic nerve fibers exit the eye.

Optical illusion See *Visual illusion*.

Optimism A general tendency to expect good outcomes.

Organizational culture The shared assumptions, beliefs, values, and customs of the people in an organization.

Organizational psychology Area of psychology concerned with how employees are integrated into the work environment, both emotionally and socially.

Organizational socialization The process by which new members are absorbed into the culture of an organization.

Outgroup People who are not part of the ingroup.

Overextension Using a word incorrectly to describe a wider set of objects or actions than it is meant to.

Overlearning Continued rehearsal of material after one first appears to have mastered it.

Overregularization In children, incorrect generalization of grammatical rules to irregular cases where they do not apply.

P

Panic disorder A type of anxiety disorder characterized by recurrent attacks of overwhelming anxiety that usually occur suddenly and unexpectedly.

Parallel distributed processing (PDP) models Models of memory that assume cognitive processes depend on patterns of activation in highly interconnected computational networks that resemble neural networks. Also called *connectionist models*.

Parallel processing Simultaneously extracting different kinds of information from the same input.

Paranoid schizophrenia A type of schizophrenia that is dominated by delusions of persecution along with delusions of grandeur.

Parasympathetic division The branch of the autonomic nervous system that generally conserves bodily resources.

Parental investment What each sex invests—in terms of time, energy, survival risk, and forgone opportunities—to produce and nurture offspring.

Partial reinforcement. See *Intermittent reinforcement*.

Participants See *Subjects*.

Passionate love A complete absorption in another that includes tender sexual feelings and the agony and ecstasy of intense emotion.

Pavlovian conditioning. See *Classical conditioning*.

Percentile score A figure that indicates the percentage of people who score below the score one has obtained.

Perception The selection, organization, and interpretation of sensory input.

Perceptual asymmetries Left-right imbalances between the cerebral hemispheres in the speed of visual or auditory processing.

Perceptual constancy A tendency to experience a stable perception in the face of continually changing sensory input.

Perceptual hypothesis An inference about which distal stimuli could be responsible for the proximal stimuli sensed.

Perceptual set A readiness to perceive a stimulus in a particular way.

Peripheral nervous system All those nerves that lie outside the brain and spinal cord.

Person perception The process of forming impressions of others.

Personal unconscious According to Jung, the level of awareness that houses material that is not within one's conscious awareness because it has been repressed or forgotten.

Personality An individual's unique constellation of consistent behavioral traits.

Personality disorders A class of psychological disorders marked by extreme, inflexible personality traits that cause subjective distress or impaired social and occupational functioning.

Personality tests Psychological tests that measure various aspects of personality, including motives, interests, values, and attitudes.

Personality trait A durable disposition to behave in a particular way in a variety of situations.

Personnel psychology See *Industrial psychology.*

Phenomenological approach The assumption that one must appreciate individuals' personal, subjective experiences to truly understand their behavior.

Phenotype The ways in which a person's genotype is manifested in observable characteristics.

Phi phenomenon The illusion of movement created by presenting visual stimuli in rapid succession.

Phobias Irrational fears of specific objects or situations.

Phobic disorder A type of anxiety disorder marked by a persistent and irrational fear of an object or situation that presents no realistic danger.

Phonemes The smallest units of sound in a spoken language.

Physical dependence The condition that exists when a person must continue to take a drug to avoid withdrawal illness.

Pictorial depth cues Clues about distance that can be given in a flat picture.

Pituitary gland The "master gland" of the endocrine system; it releases a great variety of hormones that fan out through the body, stimulating actions in the other endocrine glands.

Place theory The idea that perception of pitch corresponds to the vibration of different portions, or places, along the basilar membrane.

Placebo effects The fact that subjects' expectations can lead them to experience some change even though they receive an empty, fake, or ineffectual treatment.

Placenta A structure that allows oxygen and nutrients to pass into the fetus from the mother's bloodstream and bodily wastes to pass out to the mother.

Pleasure principle According to Freud, the principle upon which the id operates, demanding immediate gratification of its urges.

Polygenic traits Characteristics that are influenced by more than one pair of genes.

Polygraph A device that records autonomic fluctuations while a subject is questioned, in an effort to determine whether the subject is telling the truth.

Population The larger collection of animals or people from which a sample is drawn and that researchers want to generalize about.

Positive psychology An approach to psychology that uses theory and research to better understand the positive, adaptive, creative, and fulfilling aspects of human existence.

Positive reinforcement Reinforcement that occurs when a response is strengthened because it is followed by the presentation of a rewarding stimulus.

Positive symptoms Schizophrenic symptoms that involve behavioral excesses or peculiarities, such as hallucinations, delusions, bizarre behavior, and wild flights of ideas.

Positively skewed distribution A distribution in which scores pile up at the low end of the scale.

Postsynaptic potential (PSP) A voltage change at the receptor site on a postsynaptic cell membrane.

Posttraumatic stress disorder (PTSD) Disturbed behavior that is attributed to a major stressful event but that emerges after the stress is over.

Preconscious According to Freud, the level of awareness that contains material just beneath the surface of conscious awareness that can easily be retrieved.

Prejudice A negative attitude held toward members of a group.

Premises The reasons presented to persuade someone that a conclusion is true or probably true.

Prenatal period The period from conception to birth, usually encompassing nine months of pregnancy.

Preparedness Species-specific predispositions to be conditioned in certain ways and not others.

Pressure Expectations or demands that one behave in a certain way.

Prevalence The percentage of a population that exhibits a disorder during a specified time period.

Primary reinforcers Events that are inherently reinforcing because they satisfy biological needs.

Primary sex characteristics The sexual structures necessary for reproduction.

Proactive interference A memory problem that occurs when previously learned information interferes with the retention of new information.

Problem solving Active efforts to discover what must be done to achieve a goal that is not readily available.

Problem space The set of possible pathways to a solution considered by the problem solver.

Prognosis A forecast about the probable course of an illness.

Projection Attributing one's own thoughts, feelings, or motives to another.

Projective tests Psychological tests that ask subjects to respond to vague, ambiguous stimuli in ways that may reveal the subjects' needs, feelings, and personality traits.

Prospective memory The ability to remember to perform actions in the future.

Proximal stimuli The stimulus energies that impinge directly on sensory receptors.

Proximodistal trend The center-outward direction of motor development.

Psychiatrists Physicians who specialize in the diagnosis and treatment of psychological disorders.

Psychiatry A branch of medicine concerned with the diagnosis and treatment of psychological problems and disorders.

Psychoactive drugs Chemical substances that modify mental, emotional, or behavioral functioning.

Psychoanalysis An insight therapy that emphasizes the recovery of unconscious conflicts, motives, and defenses through techniques such as free association and transference.

Psychoanalytic theory A theory developed by Freud that attempts to explain personality, motivation, and mental disorders by focusing on unconscious determinants of behavior.

Psychodynamic theories All the diverse theories descended from the work of Sigmund Freud that focus on unconscious mental forces.

Psychological dependence The condition that exists when a person must continue to take a drug in order to satisfy intense mental and emotional craving for the drug.

Psychological test A standardized measure of a sample of a person's behavior.

Psychology The science that studies behavior and the physiological and cognitive processes that underlie it, and the profession that applies the accumulated knowledge of this science to practical problems.

Psychopharmacotherapy The treatment of mental disorders with medication.

Psychophysics The study of how physical stimuli are translated into psychological experience.

Psychosexual stages According to Freud, developmental periods with a characteristic sexual focus that leave their mark on adult personality.

Psychosomatic diseases Physical ailments with a genuine organic basis that are caused in part by psychological factors, especially emotional distress.

Puberty The period of early adolescence marked by rapid physical growth and the development of sexual (reproductive) maturity.

Pubescence The two-year span preceding puberty during which the changes leading to physical and sexual maturity take place.

Punishment An event that follows a response that weakens or suppresses the tendency to make that response.

Pupil The opening in the center of the iris that helps regulate the amount of light passing into the rear chamber of the eye.

R

Random assignment The constitution of groups in a study such that all subjects have an equal chance of being assigned to any group or condition.

Rationalization Creating false but plausible excuses to justify unacceptable behavior.

Reaction formation Behaving in a way that's exactly the opposite of one's true feelings.

Reaction range Genetically determined limits on IQ or other traits.

Reactivity Alteration of a subject's behavior as a result of the presence of an observer.

Reality monitoring The process of deciding whether memories are based on external sources (our perceptions of actual events) or internal sources (our thoughts and imaginations).

Reality principle According to Freud, the principle on which the ego operates, which seeks to delay gratification of the id's urges until appropriate outlets and situations can be found.

Recall A memory test that requires subjects to reproduce information on their own without any cues.

Receiver The person to whom a message is sent.

Receptive field of a visual cell The retinal area that, when stimulated, affects the firing of that cell.

Recessive gene A gene whose influence is masked when paired genes are different (heterozygous).

Reciprocal determinism The assumption that internal mental events, external environmental events, and overt behavior all influence each other.

Reciprocity Liking those who show that they like you.

Reciprocity norm The rule that people should pay back in kind what they receive from others.

Recognition A memory test that requires subjects to select previously learned information from an array of options.

Refractory period A time following orgasm during which males are largely unresponsive to further stimulation.

Regression A reversion to immature patterns of behavior.

Regression toward the mean Effect that occurs when people who score extremely high or low on some trait are measured a second time and their new score falls closer to the mean (average).

Rehearsal The process of repetitively verbalizing or thinking about information to be stored in memory.

Reification Giving an abstract concept a name and then treating it as though it were a concrete, tangible object.

Reinforcement An event following a response that strengthens the tendency to make that response.

Reinforcement contingencies The circumstances or rules that determine whether responses lead to the presentation of reinforcers.

Relearning A memory test that requires a subject to memorize information a second time to determine how much time or effort is saved by having learned it before.

Reliability The measurement consistency of a test (or of other kinds of measurement techniques).

REM sleep A deep stage of sleep marked by rapid eye movements, high-frequency brain waves, and dreaming.

Renewal effect Phenomenon that occurs if a response is extinguished in a different environment than it was acquired; the extinguished response will reappear if the animal is returned to the original environment where acquisition took place.

Replication The repetition of a study to see whether the earlier results are duplicated.

Representativeness heuristic Basing the estimated probability of an event on how similar it is to the typical prototype of that event.

Repression Keeping distressing thoughts and feelings buried in the unconscious.

Research methods Differing approaches to the manipulation and control of variables in empirical studies.

Resistance Largely unconscious defensive maneuvers a client uses to hinder the progress of therapy.

Resistance to extinction In operant conditioning, the phenomenon that occurs when an organism continues to make a response after delivery of the reinforcer for it has been terminated.

Response set A tendency to respond to questions in a particular way that is unrelated to the content of the questions.

Respondent conditioning. See *Classical conditioning.*

Resting potential The stable, negative charge of a neuron when it is inactive.

Retention The proportion of material retained (remembered).

Retina The neural tissue lining the inside back surface of the eye; it absorbs light, processes images, and sends visual information to the brain.

Retinal disparity A cue to the depth based on the fact that objects within 25 feet project images to slightly different locations on the left and right retinas, so the right and left eyes see slightly different views of the object.

Retrieval Recovering information from memory stores.

Retroactive interference A memory problem that occurs when new information impairs the retention of previously learned information.

Retrograde amnesia Loss of memories for events that occurred prior to a head injury.

Retrospective memory The ability to remember events from the past or previously learned information.

Reuptake A process in which neurotransmitters are sponged up from the synaptic cleft by the presynaptic membrane.

Reversible figure A drawing that is compatible with two different interpretations that can shift back and forth.

Risky decision making Making choices under conditions of uncertainty.

Rods Specialized visual receptors that play a key role in night vision and peripheral vision.

S

Sample The collection of subjects selected for observation in an empirical study.

Sampling bias A problem that occurs when a sample is not representative of the population from which it is drawn.

Scatter diagram A graph in which paired *X* and *Y* scores for each subject are plotted as single points.

Schedule of reinforcement A specific presentation of reinforcers over time.

Schema An organized cluster of knowledge about a particular object or sequence of events.

Schizophrenic disorders A class of psychological disorders marked by disturbances in thought that spill over to affect perceptual, social, and emotional processes.

Secondary (conditioned) reinforcers Stimulus events that acquire reinforcing qualities by being associated with primary reinforcers.

Secondary sex characteristics Physical features that are associated with gender but that are not directly involved in reproduction.

Sedatives Sleep-inducing drugs that tend to decrease central nervous system activation and behavioral activity.

Self-actualizing persons People with exceptionally healthy personalities, marked by continued personal growth.

Self-concept A collection of beliefs about one's own nature, unique qualities, and typical behavior.

Self-efficacy One's belief about one's ability to perform behaviors that should lead to expected outcomes.

Self-esteem A person's overall assessment of her or his personal adequacy or worth.

Self-referent encoding Deciding how or whether information is personally relevant.

Self-report inventories Personality tests that ask individuals to answer a series of questions about their characteristic behavior.

Self-serving bias The tendency to attribute one's successes to personal factors and one's failures to situational factors.

Semantic memory system General knowledge that is not tied to the time when the information was learned.

Semantic network Concepts joined together by links that show how the concepts are related.

Semantics The area of language concerned with understanding the meaning of words and word combinations.

Sensation The stimulation of sense organs.

Sensory adaptation A gradual decline in sensitivity to prolonged stimulation.

Sensory memory The preservation of information in its original sensory form for a brief time, usually only a fraction of a second.

Separation anxiety Emotional distress seen in many infants when they are separated from people with whom they have formed an attachment.

Serial-position effect In memory tests, the fact that subjects show better recall for items at the beginning and end of a list than for items in the middle.

Set-point theory The idea that the body monitors fat-cell levels to keep them (and weight) fairly stable.

Settling-point theory The idea that weight tends to drift around a level at which the constellation of factors that determine food consumption and energy expenditure achieve an equilibrium.

Sex The biologically based categories of male and female.

Sexual orientation A person's preference for emotional and sexual relationships with individuals of the same sex, the other sex, or either sex.

Shaping The reinforcement of closer and closer approximations of a desired response.

Short-term memory (STM) A limited-capacity store that can maintain unrehearsed information for about 20 to 30 seconds.

Signal-detection theory A psychophysiological theory proposing that the detection of stimuli involves decision processes as well as sensory processes, which are influenced by a variety of factors besides the physical intensity of a stimulus.

Skinner box A small enclosure in which an animal can make a specific response that is systematically recorded while the consequences of the response are controlled.

Sleep apnea A sleep disorder characterized by frequent reflexive gasping for air that awakens a person and disrupts sleep.

Slow-wave sleep (SWS) Sleep stages 3 and 4, during which low-frequency delta waves become prominent in EEG recordings.

Social comparison theory The idea that people compare themselves with others to understand and evaluate their own behavior.

Social desirability bias A tendency to give socially approved answers to questions about oneself.

Social loafing A reduction in effort by individuals when they work in groups as compared to when they work by themselves.

Social psychology The branch of psychology concerned with the way individuals' thoughts, feelings, and behaviors are influenced by others.

Social roles Widely shared expectations about how people in certain positions are supposed to behave.

Social skills training A behavior therapy designed to improve interpersonal skills that emphasizes shaping, modeling, and behavioral rehearsal.

Social support Various types of aid and succor provided by members of one's social networks.

Socialization The acquisition of the norms, roles, and behaviors expected of people in a particular society.

Soma The cell body of a neuron; it contains the nucleus and much of the chemical machinery common to most cells.

Somatic nervous system The system of nerves that connect to voluntary skeletal muscles and to sensory receptors.

Somatization disorder A type of somatoform disorder marked by a history of diverse physical complaints that appear to be psychological in origin.

Somatoform disorders A class of psychological disorders involving physical ailments with no authentic organic basis that are due to psychological factors.

Somnambulism (sleepwalking) Arising and wandering about while remaining asleep.

Source The person who sends a communication.

Source monitoring The process of making attributions about the origins of memories.

Source-monitoring error An error that occurs when a memory derived from one source is misattributed to another source.

Spermarche The first occurrence of ejaculation.

Split-brain surgery A procedure in which the bundle of fibers that connects the cerebral hemispheres (the corpus callosum) is cut to reduce the severity of epileptic seizures.

Spontaneous recovery In classical conditioning, the reappearance of an extinguished response after a period of nonexposure to the conditioned stimulus.

Spontaneous remission Recovery from a disorder without formal treatment.

SQ3R A study system designed to promote effective reading by means of five steps: survey, question, read, recite, and review.

Stage A developmental period during which characteristic patterns of behavior are exhibited and certain capacities become established.

Standard deviation An index of the amount of variability in a set of data.

Standardization The uniform procedures used in the administration and scoring of a test.

Statistical significance The condition that exists when the probability that the observed findings are due to chance is very low.

Statistics The use of mathematics to organize, summarize, and interpret numerical data. See also *Descriptive statistics, Inferential statistics.*

Stereotypes Widely held beliefs that people have certain characteristics because of their membership in a particular group.

Stimulants Drugs that tend to increase central nervous system activation and behavioral activity.

Stimulus discrimination The phenomenon that occurs when an organism that has learned a response to a specific stimulus does not respond in the same way to stimuli that are similar to the original stimulus.

Stimulus generalization The phenomenon that occurs when an organism that has learned a response to a specific stimulus responds in the same way to new stimuli that are similar to the original stimulus.

Storage Maintaining encoded information in memory over time.

Stress Any circumstances that threaten or are perceived to threaten one's well-being and that thereby tax one's coping abilities.

Striving for superiority According to Adler, the universal drive to adapt, improve oneself, and master life's challenges.

Structuralism A school of psychology based on the notion that the task of psychology is to analyze consciousness into its basic elements and to investigate how these elements are related.

Subjective contours The perception of contours where none actually exist.

Subjective well-being Individuals' perceptions of their overall happiness and life satisfaction.

Subjects The persons or animals whose behavior is systematically observed in a study.

Subliminal perception The registration of sensory input without conscious awareness.

Subtractive color mixing Formation of colors by removing some wavelengths of light, leaving less light than was originally there.

Superego According to Freud, the moral component of personality that incorporates social standards about what represents right and wrong.

Survey A descriptive research method in which researchers use questionnaires or interviews to gather information about specific aspects of subjects' behavior.

Sympathetic division The branch of the autonomic nervous system that mobilizes the body's resources for emergencies.

Synapse A junction where information is transmitted from one neuron to the next.

Synaptic cleft A microscopic gap between the terminal button of a neuron and the cell membrane of another neuron.

Syntax A system of rules that specify how words can be combined into phrases and sentences.

Systematic desensitization A behavior therapy used to reduce clients' anxiety responses through counterconditioning.

T

Tactile system The sensory system for touch.

Tardive dyskinesia A neurological disorder marked by chronic tremors and involuntary spastic movements.

Teams See *Work teams.*

Telegraphic speech Speech that consists mainly of content words; articles, prepositions, and other less critical words are omitted.

Temperament An individual's characteristic mood, activity level, and emotional reactivity.

Terminal buttons Small knobs at the end of axons that secrete chemicals called neurotransmitters.

Test norms Standards that provide information about where a score on a psychological test ranks in relation to other scores on that test.

Testosterone A male sex hormone produced by the testes; women secrete smaller amounts of testosterone from the adrenal cortex and ovary.

Testwiseness The ability to use the characteristics and format of a cognitive test to maximize one's score.

Theory A system of interrelated ideas that is used to explain a set of observations.

Theory of bounded rationality Simon's assertion that people tend to use simple strategies in decision making that focus on only a few facets of available options and often result in "irrational" decisions that are less than optimal.

Tip-of-the-tongue phenomenon A temporary inability to remember something accompanied by a feeling that it's just out of reach.

Token economy A system for doling out symbolic reinforcers that are exchanged later for a variety of genuine reinforcers.

Tolerance A progressive decrease in a person's responsiveness to a drug.

Top-down processing In form perception, a progression from the whole to the elements.

Transcranial magnetic stimulation (TMS) A technique that permits scientists to temporarily enhance or depress activity in a specific area of the brain.

Transfer-appropriate processing The situation that occurs when the initial processing of information is similar to the type of processing required by the subsequent measures of attention.

Transference In therapy, the phenomenon that occurs when clients start relating to their therapists in ways that mimic critical relationships in their lives.

Transformational leadership Leadership characterized by high ethical standards, inspirational motivation, intellectual stimulation, and individual consideration.

Trial In classical conditioning, any presentation of a stimulus or pair of stimuli.

Trial and error Trying possible solutions sequentially and discarding those that are in error until one works.

Trichromatic theory The theory of color vision holding that the human eye has three types of receptors with differing sensitivities to different wavelengths.

Twin studies A research design in which hereditary influence is assessed by comparing the resemblance of identical twins and fraternal twins with respect to a trait.

Type A personality Personality characterized by (1) a strong competitive orientation, (2) impatience and time urgency, and (3) anger and hostility.

Type B personality Personality characterized by relatively relaxed, patient, easygoing, amicable behavior.

U

Unconditioned response (UR) An unlearned reaction to an unconditioned stimulus that occurs without previous conditioning.

Unconditioned stimulus (US) A stimulus that evokes an unconditioned response without previous conditioning.

Unconscious According to Freud, thoughts, memories, and desires that are well below the surface of conscious awareness but that nonetheless exert great influence on behavior.

Underextensions Errors that occur when a child incorrectly uses a word to describe a narrower set of objects or actions than it is meant to.

Undifferentiated schizophrenia A type of schizophrenia marked by idiosyncratic mixtures of schizophrenic symptoms.

V

Validity The ability of a test to measure what it was designed to measure.

Variability The extent to which the scores in a data set tend to vary from each other and from the mean.

Variable-interval (VI) schedule A reinforcement schedule in which the reinforcer is given for the first response after a variable time interval has elapsed.

Variable-ratio (VR) schedule A reinforcement schedule in which the reinforcer is given after a variable number of nonreinforced responses.

Variables Any measurable conditions, events, characteristics, or behaviors that are controlled or observed in a study.

Vasocongestion Engorgement of blood vessels.

Visual illusion An apparently inexplicable discrepancy between the appearance of a visual stimulus and its physical reality.

Volley principle The theory holding that groups of auditory nerve fibers fire neural impulses in rapid succession, creating volleys of impulses.

W

Work teams Two or more employees who have common goals, pursue tasks that are interdependent, interact socially, and work within specific requirements and rules.

Z

Zone of proximal development (ZPD) The gap between what a learner can accomplish alone and what he or she can achieve with guidance from more skilled partners.

Zygote A one-celled organism formed by the union of a sperm and an egg.
